completed the baseline interview, and 90% or more of these completed each of the follow up interviews. In the 3724 person-months during which subjects had "outdoor exposure", 155 falls were reported. The incidence rates of indoor and outdoor falls were 21.2 and 20.4 falls per 1000 person-months, respectively. The table shows that the risk factors differed for indoor and outdoor falls. Our results, if confirmed, suggest that indoor and outdoor falls should be studied as separate outcomes. This distinction might eventually prove useful for the design of preventive interventions.

Remembering fractures: fracture registration and proband recall in southern Sweden

Brynjólfur Jónsson, Per Gärdsell, Olof Johnell, Inga Redlund-Johnell, Ingemar Sernbo

This study aimed to examine fracture recall and to compare different sources of information on fracture registration both within the same population and between areas. The study was carried out in southern Sweden. Altogether 782 individuals of both sexes from the city of Malmö, and 486 residents from the nearby rural community of Sjöbo were invited to participate in a population based study. A total of 570 (73%) from Malmö and 391 (80%) from Sjöbo participated. For all subjects, fracture data were obtained from three different sources — one, the probands' own recollection of previous fracture episodes and the other two, patient records. In addition, the age at the time of fracture and the severity of the trauma that caused the fracture were recorded. Where fractures were sustained and treated elsewhere and were not on our records, records from other hospitals were not studied.

Results: In Malmö, 155 of the subjects had sustained a total of 252 fractures. In Sjöbo, 75 probands had sustained 91 fractures. In Malmö 40% and in Sjöbo 22% of the fractures had been forgotten by the probands and were discovered from patient records (figure). In both communities, half of those with fractures not detailed in the records had either been treated elsewhere or had moved to their present residence since their fractures. Almost 40% of all fractures had been forgotten by the probands: in men 60% of fractures of the hand and foot and in women 22% of fractures of the distal end of the radius had been forgotten.

The median time that had elapsed between forgotten fractures and the interview was longer than that for remembered fractures: in Malmö these times were 15 and 9 years, respectively (p=0.001, Mann-Whitney) and in Sjöbo, 14 and 9 years, respectively (p=0.001). Fractures caused by more severe trauma were significantly more likely to have been forgotten in Malmö – these high energy fractures were more common in men.

Discussion: The data indicate that there will be considerable under-reporting if only one source of information is used in the screening of fractures. The cause of the discrepancy between registration and recall in the two communities may be less accurate registration in Sjöbo because people living in the outskirts of the community might have sought medical care outside of the health district.

In prospective studies, medical records have been found to confirm fracture history in all cases in women,1 but over reporting of self reported fractures has been found in 20% of cases among elderly women.2 Even in cross sectional studies similar to ours there was a tendency to over report fractures.3 Because the accuracy of a positive fracture history outside the study health districts was not examined, some of the fractures reported but not recorded may be false positives. An alternative explanation might be either better recall in rural probands, who also had fewer fractures, and fewer fractures per fractured individual,4 together with possibly more tangible effects of the fractures on the working capacity in a farming population.

Women in this study had forgotten more than one fifth of the fractures of the distal end of the radius. This is in line with the study of Åkeson et al,2 in which 14% of 36 women did not remember having sustained a wrist fracture 0-35 (mean 10) years earlier, and additionally 17% had forgotten which side they had broken.

The time elapsed since the fracture seems to be of importance for recall. In this study the median time elapsed after a remembered fracture was 9 years, whereas it was 14-15 years for

School injuries in Athens: socioeconomic and family risk factors

Eleni Petridou, Nicoletta Kouri, Dimitrios Trichopouloas, Katharine Revinthi, Yannis Skalkidis, Donald Tong

Injuries are the main cause of morbidity and mortality in childhood, and there is increasing interest in injuries at school. There is a strong socioeconomic gradient for childhood injuries and deaths. We have undertaken a case-control study in Athens, Greece, to examine the importance of family and social risk factors for injuries at school — that is, an environment not directly related to home conditions and immediate family supervision. By matching cases and controls on the school we have controlled for the contribution of factors associated with the general school situation.

Methods: Between September 1992 and June 1993 one of us was present for a total of 80 non-consecutive days at the accident and emergency clinics of one of the two major University Children's Hospitals in Athens. During this period, a total of 101 school children aged 5-14 years, resident in the Athens area, were brought to the clinics for an injury that had taken place at school and was sufficiently serious to require hospital contact. These children's schools were identified and three controls, exactly matched for school, age (single year), and gender, were randomly selected for every injury case from the respective class rosters. A standardised interview form was completed for 404 children by their teachers in collaboration with the children's families, and the variables shown in the table were assessed by modelling through conditional logistic regression.

Results: Of the 101 injuries, 49 took place in playground areas, 39 in classrooms and corridors (mostly during breaks), 10 during sporting activities, and three during transportation to or from schools. Among the injured children, three had predominantly cerebral concussion.

Multiple logistic regression-derived odds ratio estimates (and 95% confidence intervals) for school injury, associated with a series of family and socioeconomic variables
