Urinary symptoms: prevalence and severity in British men aged 55 and over

D J W Hunter, C M McKee, N A Black, C F B Sanderson

Abstract

Objective – To measure the prevalence and severity of urinary symptoms among men aged 55 and over in the British population.

Design – Cross sectional population survey using a postal questionnaire.

Setting – North West Thames health region.

Subjects – 1480 men aged 55 years and over randomly selected from 8 general practices.

Main outcome measures – Self reported frequency and severity of urinary symptoms, their bothersomeness and previous prostate surgery.

Results – The response rate among eligible subjects was 78%. The prevalence of moderate and severe symptoms was 204 per 1000, rising from 160 per 1000 in the 55–59 age group to 259 per 1000 in the 70–74 age group and declining after the age of 80 to 119 per thousand in the 85+ age group. Twelve per cent of men reported previous prostate surgery, and the probability of having had surgery increases steadily with age. About a third of those undergoing surgery have recurrence or persistence of symptoms after surgery. Of men with moderate and severe symptoms, 27–9% reported that their symptoms were a medium or big problem, 36–9% reported that their symptoms interfered with their daily activities at least some of the time, and 43–1% were unhappy or ‘felt terrible’ about the prospect of a future with their current symptoms.

Conclusion – The prevalence of urinary symptoms in men is lower than previously reported, although there is a substantial number of men who are bothered by, or who find their lives adversely effected by them.

Methods

A cross sectional population survey of the prevalence of urinary symptoms in men aged 55 years and over was carried out in North West Thames health region. This age group was selected on the basis of the results of a study in the Oxford and North West Thames regions in which more than 99% of men undergoing prostatectomy were aged 55 or more. Initially 30 general practices were selected randomly from all practices in North West Thames region and invited to participate. The 15 practices that expressed an interest in the study were sent further information and a background literature.
were you was individual's intervals number personally moderate past completely after later. The health region, Urological American appropriate database of ceding asked remaining eight they characteristics (age envelope a questionnaire sought for each practice's covering symptoms 'Over your bladder?'. A pilot version of the questionnaire, sent to 30 men selected from a general practice in the North East Thames region, achieved a response rate of 80% and led to minor modifications in the layout of the questions. For comparison, population estimates and demographic information for residents of North West Thames region were obtained from the 1991 census. Ethical approval was sought and obtained from the relevant district ethics committees.

To investigate the possible effects of response bias, general practice case notes from 100 randomly selected non-responders were compared with the case notes of 100 randomly selected responders. Information taken from these case notes included age, history of urinary symptoms, previous prostate surgery, and medical history. Reasons for the unavailability of any case notes, such as the patient having died or moved away, were recorded.

A symptom index, ranging from 0 to 30, was calculated by summing the scores of six urinary symptoms (fullness, frequency, intermittency, urgency, poor flow, and hesitancy) where each symptom was assigned one of the following values: never = 0, hardly ever = 1, less than half the time = 2, about half the time = 3, more than half the time = 4, and almost always = 5. Unlike the AUA-7 symptom index, nocturia was not included in our symptom index for three reasons: (a) it has many causes other than urinary tract disorders, such as cardiovascular disease and the person's fluid intake before going to bed, and is the symptom that responds least well to prostatectomy; (b) in a validation study of the AUA index, the highest tersymptom correlation was between nocturia and frequency, and frequency was already included in the index; and (c) the categories of nocturia severity we obtained were too crude to use. The symptom index was categorised into four levels of severity; none (0), very mild (1), mild (2–9), moderate (10–18), and severe (19–30). These cut off points were consistent with those used in a cohort study of men undergoing prostatectomy in Oxford and North West Thames region.

Data analysis consisted of frequency distributions. Confidence intervals for proportions were calculated at the 95% level using the method of Fleiss. Patterns of symptoms and surgical status based on age by individual years were smoothed using five point moving averages.

Notes on table: (1) Missing data are not included in column totals. (2) Population estimates for North West Regional Health Authority are taken from the OPCS 1991 Census, County Monitors.

A two page questionnaire, together with a personally addressed covering letter from the individual's general practitioner and a stamped, addressed envelope for reply, were sent to each man. Non-responders were sent a reminder letter and a second questionnaire one month later. The questionnaire sought information about the men's sociodemographic characteristics (age and ethnicity) and any urinary symptoms they had experienced over the preceding month. Questions on urinary symptoms were taken from the recently published American Urological Association (AUA) symptom index, with some minor modifications to the wording of the questions to make them more appropriate to a British population. For example, the AUA question on fullness 'Over the past month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating?' was changed to 'In the past month, how often did you feel that your bladder did not empty fully after urinating?'.

Urinary symptoms: prevalence and severity in British men aged 55 and over

**RESULTS**

**CHARACTERISTICS OF THE SAMPLE**

Of the 2000 men who were sent a questionnaire, 21 had died and 74 were unknown at the address in the general practice records, so that the final study population was 1905. The response rate after the first mailing was 64%, rising to 78% (1480 returned questionnaires) after a postal reminder. The age structure of those responding was similar to that of all men living in North West Thames region, except for those in the 55 to 59 age group, who seemed to be under-represented in our sample (table 1). Responders were more likely to be white than would be expected from the male population in this age group.

The comparison of subsamples of responders and non-responders (table 2) found no difference in mean age. Apparent non-responders included 8% who had either died or moved or for whom the general practitioner had no evidence of a medical record. In addition, for 2% of responders and 11% of non-responders, although there was evidence that a record existed, these records could not be located. Comparison of the medical records available showed that responders were more likely to have undergone previous prostate surgery (7% v 1%; p<0.05), but there was no significant difference in their medical histories of urinary symptoms.

**PREVALENCE AND SEVERITY OF SYMPTOMS**

The distribution of each urinary symptom in relation to the level of severity is shown in figure 1. Most men report that they never, or hardly ever, experience these symptoms. The distribution of the symptom index is also strongly skewed to the left (fig 2); few men experience high composite symptom scores. On categorising the data, 20-8% report no symptoms, 10-4% very mild symptoms, and 48-5% mild symptoms (table 3). The overall proportion of men with moderate/severe symptoms was 20-4%. This increased from 16-2% in those aged 50 to 59 years to a plateau of between 20 and 25% in the age group between 65 and 79. It then fell to 11-9% in the over 85s.

**IMPACT OF SYMPTOMS**

The extent to which men were bothered by their symptoms increased significantly with increasing symptom severity (table 4). Of those with very mild and mild symptoms, only 0-5% felt they were a medium or big problem; this increased to 15-9% of those with moderate symptoms and 66-2% of those with severe symptoms. Of those with moderate symptoms, 2-8% reported interference in their daily activities most or all of the time (table 5). This increased to 17-9% for those with severe symptoms. When asked about spending the rest of their life with their current symptoms, 11% of men reported they would feel unhappy or terrible (table 6). This proportion varied in relation to symptom severity from 3-5% of those with very mild and mild symptoms to 76-4% with severe symptoms.

**PREVIOUS PROSTATE SURGERY AND OTHER UROLOGICAL SYMPTOMS**

The prevalence of urinary symptoms will partly depend on prostatectomy rates in the past and the effectiveness of this surgery. Altogether 164 (12%) men reported having undergone previous prostate surgery (table 7). To allow for...
the different numbers of men at risk of having surgery, the probability of having surgery when in each age group was calculated by dividing the number of men who had surgery when in each age group by the number of men that had reached that age group (table 7). The probability of having surgery when under 50 years of age was only 0.1% and increased to 8% in the age group 75 to 79 years. This is equivalent to a doubling in the probability of having surgery every five years. Because there are fewer men in older age groups, this gives a different picture to that seen in urological practice. Almost half (45-7%) of the men who had undergone surgery were aged between 60 and 69.

Of the 156 (6%) men who reported a previous episode of acute retention, only 38-5% had undergone surgery (table 8). Altogether 8% of men reported a previous urinary tract infection. When asked about urinary in-continence, 7-5% leaked enough urine to be embarrassed, and 0-8% needed to wear pads.

### SUMMARY

The current pattern of urinary symptoms in men aged 55 and over and the urological response to them is best illustrated by combining the data on the prevalence of men with a history of prostate surgery (table 7) and the prevalence of urinary symptoms (table 3). Figure 3 shows the proportions of men in each age group in each of the following states: (a) no, very mild, or mild symptoms and no previous surgery; (b) moderate/severe symptoms but no previous surgery; (c) previous surgery with no current moderate/severe symptoms; and (d) previous surgery and current symptoms. The percentage of men with either moderate or severe symptoms or a history of previous prostate surgery, or both, increased from 17% at age 57 years

N = 1480, 99 missing; percentages have been rounded.
to 38% at age 81. The percentage of men with moderate/severe symptoms who have not had prostate surgery increases until the age of 73 and then seems to decrease. Of men who have had prostatectomy, the percentage with recurrence or persistence of moderate or severe symptoms seems to remain relatively constant across the age range, at about 30%.

Discussion
This study has described the prevalence and severity of urinary symptoms in British men aged 55 and over. Although most men report no urinary symptoms, 20% reported moderate or severe symptoms. Of these, only 28% found their symptoms a medium or big problem. Thirty seven per cent experienced interference with their daily activities at least some of the time, and 43% would be unhappy at the prospect of a future with their symptoms continuing at their current level.

Before any conclusions may be drawn, the limitations of this survey should be considered. Men in the 55 to 59 year age group were under-represented compared with the general population, although comparison of the mean age of responders and non-responders suggests that this may have been due to characteristics of the practices studied rather than a difference in response rate.

Secondly, those who do not respond to surveys may differ in some way from those who do. From the examination of case notes we found that 8% of men who did not respond had died, moved, or had no general practice medical records. This suggests that our true response rate may have been as high as 80%. Non-responders did not differ from responders in terms of their history of urinary symptoms as recorded in the general practice records but they were less likely to have had previous prostate surgery.

Thirdly, the way the questions were phrased could bias the results. The AUA symptom index for the symptoms of benign prostate hyperplasia has been extensively tested and has been shown to be internally consistent and have good test-retest reliability, as judged by Pearson correlation coefficients. Symptom severity categories were derived from cut off points used in a previous study. The use of different cut offs would have important implications for the numbers of individuals in each category. For example, we defined moderate or severe symptoms as a symptom index of greater than 9, giving a prevalence in the male population aged 55 and over of 204 per 1000. Reduction of the threshold to 8 would result in a prevalence of 227 per 1000; a threshold of 11 would result in a prevalence of 170 per 1000.

Our survey measured the felt need for treatment rather than the normative need. The clinical decision to offer treatment is based on a combination of urinary symptoms and the results of urological investigation. Assessment of normative need is complicated by the absence of an accepted definition of benign prostate hyperplasia. Currently, there is a debate in the urological literature about the importance of each. Several studies have shown a poor correlation between symptoms and objective urological measures such as flow rates and residual volume. Given that most surgery

</table>
is carried out to improve a man's quality of life, we therefore believe that the presence of
urinary symptoms is an essential, though not
the only, factor that should be measured when
assigning the need for surgery in the population.

It has been suggested that there is a large
proportion of men in the British population
with undiagnosed but symptomatic pro-
statism.\(^7\) Our study supports this view. The
only other study on the prevalence of urinary
symptoms in men in the UK has been reported by
Garraway et al. They reported a prevalence
in men aged 40–79 years of 104 per 1000.\(^8\)
These figures refer to men with a symptom
score of at least 11 out of a possible 48 points
(eight symptoms each with a maximum score of
six). If we were to use an equivalent cut-off
point with our data, 7 out of 30, we would
produce a prevalence of 292 per 1000. How-
ever, some important methodological differ-
ences between the two studies remain. In the
study by Garraway et al., the men were younger
(over 50% were under 55 years), 9% of men
in the study population were excluded, and the
response rate was lower (only 64%\(^9\) compared
with 78%). All of these might explain why they
obtained a lower estimate of prevalence than we
did. These factors could therefore reconcile
our results with theirs.

The finding that 61·5% of men with a history
of acute retention had not undergone surgery
indicates that the view that this is an almost
absolute indication for surgery\(^10\) is no longer
held. This finding is consistent with the views
of a consensus panel on the appropriate in-
dications for prostatectomy that was held re-
cently.\(^21\)

These results and evidence from other stud-
ies suggest that prostatism begins to develop
in some men under the age of 50. Although
we based our sample on evidence that pro-
statectomy was almost never performed on men
under the age of 55, the relatively high pre-
valence of moderate or severe symptoms among
men in the 55 to 59 age group indicates that
future studies should include younger men.
This is consistent with the population based
survey by Garraway et al. that described the
onset of urinary symptoms among men in their
40s\(^7\) and a review of necropsy data by Berry et
al suggesting that the first changes in prostatic
weight appear in men as young as under 30.\(^22\)
From the age of 55 until the early 70s, the
percentage of men with moderate or severe
symptoms who have not had surgery increases
slowly from 15% to 20%, decreasing thereafter.
A few individuals have surgery under 50, but
the probability of surgery only exceeds 1% in
the 55 to 59 age group. Thereafter it increases
steadily. This leads to a progressive increase
in the number of men who have had surgery
by the age of 85. Of those who have had surgery,
the proportion who have residual or recurring
symptoms is roughly constant. The figure
of about a third in this study is higher than that
found in two cohort studies of men undergoing
surgery\(^13\) but both followed up patients for
only one year. Some of the men in our survey
had surgery up to 10 years previously.

These results suggest that prostatism, shown
by the prevalence of either urinary symptoms
or a past history of prostatic surgery, increases
steadily throughout middle and old age, with
the first signs appearing under the age of 55
and with almost 40% of men having been
affected by the age of 80. After 80, the pre-
valence of prostatism does not increase further,
and may actually decrease. These findings may
occur by chance because there were only 29
men over the age of 80 in our sample with
moderate or severe symptoms, but if the sug-
gested decrease is true, there are three possible
explanations. The first is that some cases of
benign prostate hyperplasia resolve sponta-
aneously. This has been suggested by other
authors, although there is no strong empirical
supporting evidence.\(^24\) Secondly, most of those
men who are going to suffer from benign pro-
state hyperplasia begin to do so by the time
they reach 80, and the population contains
subgroups with varying susceptibilities to the
disease. Some support for this hypothesis
comes from a review of series of necropsy data
that suggested that at least 10% of men have
no histological evidence of benign prostate hy-
perplasia.\(^25\) The third possibility is that men
with benign prostate hyperplasia have a reduced
life expectancy, leading to selection out of the
population in this age group. If the last of these
is true, it could be due to either the effects of
the disease or the complications of treatment.
This explanation is consistent with the results
of the study by Wennberg et al that suggested
that transurethral prostatectomy was associated
with an increase in mortality compared with
men not undergoing surgery.\(^25\) If any of these
suggestions, or a combination thereof, are true
there are important implications for urology
research and practice, especially as new treat-
ments designed to prevent the development of
benign prostatic hypertrophy becomes avail-
able. For example, it would be useful to com-
pare the characteristics, such as differences
in androgen responsiveness, of those men who
will and will not suffer from benign prostate
hyperplasia.

About 20·4% of men have moderate or
severe symptoms, this does not reflect the de-
gree of concern that they express. Only 5·9% of
men report that their symptoms are a me-
dium or big problem and 1·5% report that they
interfere with their daily activities all or most
of the time. In contrast, 10·9% feel unhappy
or terrible about the prospect of a future with
their current level of symptoms, indicating a
difference between the extent to which men
are affected at present and how they would like
to be in the future. A possible explanation for
this is that men are able to cope with their
existing level of symptoms but feel that they
will be unable to do so in the future as they
become older and more infirm. This is sup-
ported by evidence from a study of women
suffering from urinary incontinence.\(^27\)

How will the results of this study be used?
A second survey of those men who reported
moderate or severe symptoms has been un-
dertaken. This will report on the ways that
their symptoms affect their health status and
whether or not they would choose to have surgery. When combined with information on clinicians’ views of appropriateness and patient preference for treatment, these data will provide estimates both of the normative need for treatment and demand in the population and inform planning of the provision of urological services.

This work was funded by the Locally Organized Research of the North West Thames Regional Health Authority. We are grateful to the collaborating general practitioners who participated in the study and to all of the men who completed the questionnaire.
