THEORY AND METHODS

Missing, mediocre, or merely obsolete? An evaluation of UK data sources for coronary heart disease

B Unal, J A Critchley, S Capewell

Study objective: Coronary heart disease (CHD) is the commonest cause of death in the UK. Therefore, there is a need for comprehensive source of information to support CHD prevention and treatment strategies. This study aimed to evaluate the availability and quality of UK CHD data sources.

Design: Data sources for England and Wales were identified and appraised on:
1. CHD patient numbers (myocardial infarction, angina, hypertension, and heart failure);
2. Uptake of medical and surgical CHD treatments;

Setting: England and Wales (population 53 million).

Main results: Population and mortality data were easily accessible from Office for National Statistics and British Heart Foundation's Annual CHD Statistics. Population-based risk factor data came principally from the British Regional Heart Study, the General Household Survey, and the Health Survey for England. They were limited for 1981, but more extensive by 2000. Hospital admissions information since 1998 was available online from HES; but trend data and details of interventions were scant. Limited primary care data on consultation rates, prescribing, and treatment uptake were available from published audits and studies.

Conclusions: Information on CHD in the UK is fragmented, patchy, and mixed in quality. Data for women, the elderly population, and ethnic minorities were particularly scarce, exacerbating inequalities. Future CHD disease monitoring and evaluation will require comprehensive and accurate population-based information on trends in patient numbers, treatment uptake, and risk factors.

Policy decisions on health and health care increasingly require good evidence, particularly as resources are limited. Good evidence to describe the current situation means not just information on the effectiveness of interventions, but also valid and reliable data on the disease burden and the provision of health care.

Coronary heart disease (CHD) is the commonest cause of death in the UK. CHD mortality rates have halved in most industrialised countries since the 1970s. However, mortality has declined less in the UK, and CHD still generates a massive burden.

Methods

UK data sources on CHD were initially identified and categorised according to the IMPACT CHD mortality model, which aims to explore CHD mortality trends in England and Wales during 1981–2000.

To build the IMPACT Model, information was required on:
(a) Population-based mortality rates;
(b) Patient numbers with different categories of CHD—acute myocardial infarction, unstable and chronic angina, heart failure, hypertension, coronary artery by pass graft (CABG) surgery, and angioplasty;
(c) Uptake of specific medical and surgical treatments;
(d) Effectiveness of specific cardiological treatments and risk factor reductions;
(e) Population trends in major cardiovascular risk factors (smoking, cholesterol, hypertension, obesity, diabetes, physical activity, and deprivation).

Data were identified and obtained by various methods including comprehensive Medline search using keywords and MeSH headings, searching conference proceedings, audit reports, online search of possible official web sites, and personal correspondence (details available from authors).

The main data sources for population and mortality data were the Office for National Statistics (ONS) and the British Heart Foundation's Annual CHD Statistics. Information on treatment prescription and uptake was obtained from various national and local clinical audits and surveys.

Data on efficacy of interventions and risk factor changes were reviewed from published randomised controlled trials, meta-analyses, and population studies.

The British Regional Heart Study, General Household Survey, and Health Survey for England were the main data sources for risk factor data.

Each data source was evaluated by two researchers using a standardised approach based on the following criteria: coverage and completeness (population of interest), coding accuracy (where these were reported in the primary data source), validity (the degree to which a variable measures what it purports to measure)—where this was reported in the primary data source)—and generalisability (critical appraisal...
of the studies for their methodology), ease of access (availability of information either published or electronically), and inclusion of information on age and sex breakdowns, ethnic, and socioeconomic categories.

RESULTS
Population and patient data sources
Table 1 gives the main data sources for population and patient data.

Data from ONS official statistics13–16 were easily accessible both electronically and in published form. The British Heart Foundation provided another very useful source of annually updated CHD statistics for the UK.8

Information on patient numbers undergoing CABG surgery has been available from the United Kingdom Cardiac Surgical Register since 1977.7 The register was based on voluntary and anonymous reporting of activity and hospital mortality for CAVG, valvular, and congenital heart disease surgical procedures performed in NHS hospitals. Each unit was asked to return a standard questionnaire annually to the Society of Cardiothoracic Surgeons.7 These data were then analysed and published as annual reports. However, while reasonably complete, the register lacks details on age, sex, ethnicity, social status, and long-term survival.

Angioplasty patient numbers have been available from the British Cardiovascular Intervention Society’s Audit returns since 1977, and from British Heart Foundation Annual CHD Statistics online or published reports.2 Little information on ethnic minority or socioeconomic differences.

CHD mortality rates
Available as mortality statistics from Office for National Statistics6 and from British Heart Foundation Annual CHD Statistics online or published reports also available from Hospital Episode Statistics (HES).

CABG surgery patients (number)

Angioplasty patients (number)
Angioplasty numbers for 1991–2000 available online on British Cardiovascular Intervention Society’s website http://www.bcis.org.uk/audit/Bcis00.ppt.20 Age and sex split not provided. No long term survival.

Angina patients admitted to hospital (number)

Angina patients in the community (number)
Prevalence of “ever experienced angina” is available from Health Survey for England 1998,13 and British Regional Heart Study.65 Only prevalence not incidence.

Heart failure patients admitted to hospital (number)

Heart failure patients in the community (number)
Prevalence of treated heart failure patients in the community available from Key Heart Statistics from General Practice 1998 report23 GP consultations; therefore omits subjects not presenting to NHS.

The database contained information on diagnoses, operations, admission method, patients’ age, sex and ethnic group, length of stay, waiting time, maternity care, psychiatric care, Health care Resource Groups (HRGs), NHS Trusts, and health authority areas.5 However, HES could not provide details of the drugs used in hospitals, nor information concerning outpatients or patients treated in accident and emergency departments and then discharged home immediately. HES records described episodes of continuous inpatient care and then discharged home immediately. HES records described episodes of continuous inpatient care under the same consultant.21 In cases where responsibility for a patient’s care transferred to another consultant, there would be two or more records for the same patient. In 1999–2000, about 8% of spells fell into this category.21 Another important limitation of the database was being unable to distinguish between first admissions and readmissions.

The number of angina patients in the community could be estimated using the prevalence of “ever experienced angina”, available from the Health Survey for England 98.13 This was a series of annual surveys about the health of people in England carried out since 1991. The Health Survey for England contained a “core”, which was repeated each year, and each survey year has one or more modules on subjects of special interest. The Health Survey for England 1993, 1994, and 1998 had cardiovascular disease modules and could therefore provide useful information on CHD, stroke, hypertension, and other cardiovascular risk factors.

The number of heart failure patients in the community was principally estimated using prevalence of “treated heart failure” from Key Heart Statistics from the General Practice Research Database, 1998.14 This report gave the prevalence of various morbidities and treatment data derived from general practitioner medical records. It provided data for age-sex groups. However, as this source was based on general practitioner consultations, it omitted those symptomatic subjects who did not present to the NHS, but who would be detected by epidemiological surveys.21-24
Cardiovascular risk factor data sources

Table 3 gives the population based cardiovascular risk factor data sources and their evaluations.

The risk factors considered were smoking, total cholesterol levels, blood pressure, physical activity, obesity, diabetes, and deprivation. Population based risk factor data, either distribution (mean, standard deviation) or prevalence, were available principally from the British Regional Heart Study, the General Household Survey, and the Health Survey for England. Information was very limited for the 1980s, but more extensive by the year 2000.

Blood pressure data were limited until recent times. The British Regional Heart Study provided some blood pressure data in 1981, but only for men aged 40–59. The Dietary and Nutritional Survey of British Adults was another source for blood pressure data from 1990 onwards and provided sex and limited age breakdowns (under 65). The Health Survey For England has included blood pressure data since 1993.

Data on cholesterol levels were very limited during the 1980s. The Health Survey For England included cholesterol levels from 1993. However, changing laboratory methods used between surveys made the interpretation of recent trends difficult, even when supported by trend data from the MONICA surveys based in Scotland and Northern Ireland.

Data on obesity (defined as BMI ≥ 30 kg/m²) were available from two Department of Health surveys in the early 1980s. Data on other anthropometric measures such as waist to hip ratio, were not available in early 1980s but only from more recent population surveys.

Some indirect evidence of a decline in physical activity (an increase in car journeys and decrease in miles walked) was available from the Department of Transport’s Transport Statistics for Great Britain. However, no comprehensive population based measures were available before the Allied Dunbar Survey in 1990. The British Regional Heart Study provided physical activity data limited to men aged 40–59. The Health Survey for England included physical activity questions since 1991 with revisions in 1997 and 1998. Furthermore, definitions of physical inactivity have varied in different surveys so comparable trend information were generally not available.

Smoking prevalence was the exception among the cardiovascular risk factors with good data trends easily available from successive General Household Surveys and the British Household Panel Surveys. Age, sex, and socioeconomic breakdowns were also available.

There were some studies on diabetes starting from the 1970s, mainly focusing on treatment efficacy (The United Kingdom Prospective Diabetes Study) and mortality in...
since 1991.

provided self reported information on diabetes prevalence

DISCUSSION

However, early information on trends in diabetes

prevalence was available only from one population survey in

Poole starting in 1983. The Health Survey for England

provided self reported information on diabetes prevalence

since 1991. Trends in general practice consultations between

1994 and 1998 recently became available from the General

Practice Research Database.

Socioeconomic information was available on household

income, adjusted for tax and benefits, and housing tenure from

various sources including Social Trends and the General

Household Survey. However, because deprivation scores

describe relative deprivation on the basis of cross sectional
data, trend data for deprivation scores have not been
generated. Data on socioeconomic characteristics, defined as
occupation of head of household, equalised income, and
health authority area type were available from the Health
focused on ethnic minority groups in England, and provided
some relevant data for these groups.

Available information on CHD in the UK is frequently patchy, obsolete, or simply not available. Although routinely collected data provide large quantities of health information, often covering the whole population over a long period of time, such sources have limitations and are underused. The Office for National Statistics provides useful updated population and mortality statistics. Much of the Office for National Statistics information is available electronically, which makes it much more accessible for users. Likewise Hospital Episode Statistics, which summarise admissions to the NHS hospitals, but which lack detail on interventions.

Public health information on coronary heart disease in England must be improved. At present, the NHS annually spends over £2 billion on a range of evidence based initiatives for the treatment of CHD. However, evaluation of these initiatives using existing routine data is simply not possible. Furthermore, monitoring this common and devastating disease is generally confined to analysis of mortality statistics. Over 35 000 CABG operations are performed each year, however survival even two years later is not routinely available. Thirty day case fatality after admission for acute myocardial infarction or CABG surgery have been used as Department of Health performance indicators. However, variations in performance indicators between individual hospitals are vulnerable to differences in coding practices and case mix.

To review CHD data sources in all countries is beyond the scope of this paper; however, some international comparisons are extremely useful. Northern European countries have developed and implemented better CHD monitoring systems.

CHD mortality rates in Finland were once the highest in the world. A series of regional risk factor surveys (FINRISK)
have been carried out there every five years since the early 1970s. These use a standardised methodology, include all the important CHD risk factors, with high participation rates and a large sample size (about 14,000 for the 2002 survey). Reliable estimates of trends and their contributions to CHD mortality declines can therefore be made over a 30-year period. These surveys also permit comparatively quick identification of adverse developments such as the increase in smoking among women.

Monitoring of risk factors and of secular trends in risk factor epidemiology is also available in Norway. Cardiovascular risk factor studies have been conducted in different regions since the late 1950s. Since the 1970s, the National Health Screening Service (SHUS) cardiovascular disease screening and prevention programmes visit all municipalities every three years, and achieve high response rates.

In the USA, the National Health and Nutrition Examination Survey (NHANES) has been periodically conducted since the early 1960s to obtain nationally representative information on health, nutritional status, risk factors, and health behaviours in the population. NHANES III (1988–94) is the seventh of these.

The Information and Statistics Division (ISD) in Scotland collects good data on all patients treated for CHD and the procedures received. Scotland’s routine NHS data are of high quality and data linkage permits the investigation of the epidemiology and treatment of heart disease across the population, with comprehensive analyses then being possible on different forms of the disease, including myocardial infarction and heart failure. In England and Wales, the CHD NSF, NHS Plan, and CHD Information Strategy now explicitly recognize the huge importance of disease monitoring and service evaluation. All have made a number of specific and sensible recommendations. However, at present over 99% of the £2 billion NHS CHD budget is spent on medical interventions, particularly revascularisation. Less than 1% is currently spent on the monitoring of CHD. These are inadequate resources for even basic information strategy or information technology. Periodical surveys could provide valuable information about the risk factor trends in the population. In addition, a system of disease registers of individual data, which can be linked, as in some Scandinavian countries would help to detail medical interventions and monitor their effectiveness. Furthermore, although some national data collections (such as the Health Survey for England) can support the Information Strategy, such datasets are not “locally owned” and lack the scope to analyse specific population groups, such as ethnic minorities.

CONCLUSION

Future CHD disease monitoring and evaluation will require comprehensive and accurate population-based information on trends in patient numbers, treatment uptake, and risk factors. This will require adequate resources to improve existing information systems. Regular and comprehensive surveys (including women, elderly people, and ethnic groups), using standardised methodology will also be essential. Until then, there is a very real risk that NHS CHD strategies will blunder into the dark.
