Physical functioning in elderly Europeans: 10 year changes in the north and south: the HALE project

Sinikka Äijärne, Irma-Leena Notkola, Marja Tijhuis, Wija van Staveren, Daan Kromhout, Aulikki Nissinen

Objectives: To examine age related changes in physical functioning in elderly men and women.
Design: Prospective, population based study.
Setting: Population of 15 rural and urban centres in 10 European countries.
Participants: Altogether 3496 men and women born between 1900 and 1920 who participated in the baseline survey of the HALE project in 1988–1991. The study population was examined again about five (in 1993–1995) and 10 (in 1999–2001) years after the baseline examination.
Main outcome measures: Physical functioning was measured by means of a self administered questionnaire of activities of daily living (ADL). Dichotomised prevalence of disability and need for help in self care and mobility ADL were used as dependent variables in the analyses.
Results: Prevalence of disability and need for help tended to be higher in women than in men and in mobility abilities than in self care activities. Disability and need for help increased with advancing age but ameliorated over time from one birth cohort to another. In longitudinal analyses this beneficial time trend was independent of the effect of age, study, and region in self care disability in men and women (OR 0.85, 95% CI 0.75 to 0.97 and OR 0.64, 95% CI 0.43 to 0.97, respectively) and self care need for help in men (OR 0.83, 95% CI 0.70 to 0.96). Mobility disability among men and self care disability among women decreased more in the south than in the north.
Conclusion: While European populations are aging, the proportions of elderly people with disability are decreasing. These results suggest that dynamics of functioning may differ across cultures. Future studies are needed to clarify which potentially modifiable and culturally determined factors protect against functional decline.

Methods

Study population
The HALE project is based on data from two population studies, the FINE study (Finland, Italy and the Netherlands elderly) and the SENECA study (survey in Europe on nutrition and the elderly, a concerted action).

The FINE study is a continuation of the seven countries study (SCS), first initialised in the late 1950s to study cardiovascular mortality and morbidity in seven different countries. The fieldwork of the SCS was closed after 25 years but the survivors of the original study cohorts in Finland, Italy, and the Netherlands were invited to re-examinations in 1984–1985 and again after 5, 10, and 15 years in the context of the FINE study. In these surveys, measures of physical functioning, mental health, diet, and overall health status were included in the original SCS study protocol. The study population of the FINE study consists of men born between 1900 and 1920.

The SENECA study focuses on cross cultural differences in dietary patterns and lifestyle factors affecting health and functioning in elderly Europeans. The subjects were selected...
from a random age and sex stratified sample of inhabitants from 15 European towns. Subjects living in psychogeriatric nursing homes were excluded. At baseline in 1988 men and women born between 1913 and 1918 were invited to the study. Follow up surveys were performed in 1993 and 1999. In this study five of the 15 centres were excluded because only baseline data were available from them.

Around 3500 men and women examined in 1988–91 in the context of FINE and SENECA studies are included in the HALE database. The general objective of the HALE project is to study cultural differences and changes in and determinants of physical, psychological, social, and cognitive aspects of health and functioning in elderly Europeans. To enable cross cultural comparison the study population was dichotomised into north and south based on dietary and health related lifestyle factors. Figure 1 shows how this study population (n = 3496 at baseline) was formed, study centres by region and study, numbers of subjects per study, numbers of deceased between examination years, participation rates, and activities of daily living (ADL) participation rates.

The initial participation rate in the FINE study was quite high (76.3%) but in the SENECA study less than 50% of men and women initially invited to the participated in the baseline examinations. In both regions, north and south, participation rates varied from about 40% to 60% between centres.

**Measurements**

Physical functioning was measured by self administered questionnaires on capacity to perform ADL. These questionnaires are adapted from a standardised World Health Organisation questionnaire. Twelve items identical in the 17 item version used in SENECA and the 14 item version used in FINE were included in the HALE database.

The level of competence in each of these items was measured on a four point scale: (1) able to do without difficulty, (2) able to do with difficulty but without help, (3) able to do only with help, (4) unable to complete. For the purpose of this study, two ability scores were calculated: self care ADL and mobility ADL (see appendix 1 for details).

For the purpose of this study the sum scores in both domains (self care and mobility abilities) were dichotomised into two outcome variables: disability (difficulty) in performing one or more of the items constituting the sum score (coded as 1) compared with no disability in any of the items (coded as 0) and need for help in one or more of the items (coded as 1) compared with no help needed (coded as 0) in performing these activities. Disability in performing a task

---

**Figure 1**  Formation of the study population. *n* = (a) Total number of survivors in the original study cohorts; (b) total number of persons invited to the study. †PR = (a) participation rate at baseline (number of participants / n*, or n²); (b) participation rate at follow up (number of participants/ n§). ‡ADL = % (number) of completed ADL questionnaires. §n = number of survivors among baseline participants.
can be regarded as subjective experience of coping whereas need for help is an indicator of outside assistance needed, whether provided by the healthcare system or family members. Based on the hierarchical order of the three ADL domains it is justifiable to conclude that disability or need for help in self care abilities in this population is indicative of moderately severe or possibly even severe functional impairment.

In this study, FINE and SENECA study populations were first analysed separately. However, as the differences between the two databases with respect to disability and need for help prevalences and magnitude of changes were small and statistically not significant, the final analyses were performed for the study population as a whole. As the Netherlands had a centre in both FINE and SENECA study we ran sub-analyses in Dutch data to check comparability of the ADL questionnaires between the two studies. We found no significant differences in prevalence levels or magnitude of changes between the two Dutch centres.

**Statistical methods**

The presence of functional disability and need for help at the three examination points are described by age specific prevalence rates calculated separately for men and women by region. The $\chi^2$ test was used to test the differences between age groups and the two regions.

In modelling the data, all cross sectional measurements for the study persons were included, and logistic generalised estimating equation (GEE) models that take into account the dependence between repeated measurements within the same person were used, by the XTGEE procedure of Stata 7.0. Separate models were fitted for dichotomised disability and need for help in self care and mobility, separately for men, women, and both sexes. The dichotomised outcome variables were used because the outcome measures were not normally distributed. Follow up period, age (years) as two terms (age and age$^2$), study (1 = SENECA, 2 = FINE) and region (1 = north, 2 = south) were entered into the models as covariates. In the models for both sexes only SENECA data were included, to ensure the comparability of the data; as mentioned above, women were not included in the FINE study.

The data were analysed with statistical packages SPSS (version 11.5 for Windows) and Stata (version 7.0). p Values below 0.05 were regarded as significant. Two tailed tests were used when appropriate.

## RESULTS

Of the total study population 59% lived in northern and 41% in southern Europe. The average age and educational level were higher in the north than in the south (table 1). Subjects in the north rated their health and physical activity slightly better in relation to others of same age. No significant regional differences were found with respect to living or marital status. Tables 2A and 2B show, respectively, the prevalences of disability and need for help in the two domains by age group and region. Throughout the follow up, both sexes reported higher prevalence of disability than that of need for help in all age groups in both regions. In both domains disability and need for help increased towards higher age groups in all study years. In mobility activities the prevalence of disability varied from one third in the youngest up to 100% in the highest age groups but help was needed by roughly one half of those reporting disability. Disability and need for help in self care abilities was less common than in mobility abilities. During the follow up disability and need for help increased with age in all baseline age groups in both domains and both sexes.

Figures are % (N). Significance of trend, tested with $\chi^2$ test for linear trend: *p<0.05; **p<0.001.
Odds ratios and confidence intervals derived from logistic regression models are shown for disability in table 3A and for need for help in 3B. The association of age with disability and need for help was curvilinear and seemed stronger in men than in women. Region showed some association with the outcome measures in favour of the south. The effect of region was independent of age and study in mobility activities in both sexes and in self care abilities in women in the longitudinal model.

Viewed from a time series perspective, the figures in tables 2A and 2B suggest a beneficial trend towards better functioning in similar age groups over time. Within similar age groups, proportions of subject with disability and need for help tended to be lower in the follow up surveys than at baseline, especially in the south (table 2A, B). In the longitudinal GEE analysis the beneficial trend over time remained significant in self care disability (OR 0.85, 95% CI 0.75 to 0.97 in men and OR 0.64, 95% CI 0.43 to 0.97 in women) and self care need for help (OR 0.82, 95% CI 0.70 to 0.96 in men) even when age, study and region were controlled for. We also found a statistically significant interaction between region and follow up in mobility disability in men and self care disability in women (results not shown). Thus, among men the age and study adjusted prevalence of mobility disability decreased more in the south than in the north during the follow up. Among women, the same was true for self care disability. Adjusted for age, region, and follow up women had higher prevalence of disability in both domains and in need for help in mobility abilities (p values 0.001, <0.001, and <0.001, respectively in GEE analysis, results not shown) when compared with men.

**DISCUSSION**

This 10 year longitudinal study shows that in the course of the 1990s physical functioning of European men and women aged 70+ at baseline declined with age especially among men but ameliorated in succeeding birth cohorts over time. When age, study, and region were controlled for, this beneficial trend remained statistically significant in self care disability in both sexes and in need for help in mobility abilities (p values 0.001, <0.001, and <0.001, respectively in GEE analysis, results not shown) when compared with men.
The two geographical regions we found differences showing a more favourable time trend in the south than in the north of Europe.

Some potential confounders should be kept in mind when interpreting the results. Selective drop out attributable to death must always be taken into account when interpreting health changes in the elderly population. However, this is more likely to have levelled off the age effect than to have emphasised it. On the other hand, the main purpose of this paper was to study the trends of disability at population level among the surviving elderly population.

Poor physical functioning is predictive of non-response. Subjects who participated in the surveys may thus have been healthier and more active than those who did not but it is difficult to evaluate the magnitude of the impact of low response rates on the time related changes seen in this study. With comparatively high follow up response rates this is unlikely to have biased the results. Because of low initial participation rates in some centres, this issue is especially relevant in SENECA data. The most common reasons reported for baseline non-participation in SENECA were no time/interest to participate and illness (75% and 12% of non-participants, respectively).

Confounding attributable to unknown cultural (that is, culturally defined norms), life circumstantial or socioeconomic factors, or factors such as type and availability of care for the elderly is possible but it is difficult to estimate to what extent they may have affected the results. Changes in socioeconomic conditions and availability of care may follow different patterns in different countries. Not accounting for these factors in this study may have affected the point estimates of the impact of age and follow up on functioning but it is unlikely that it has biased the trends seen in our study. The countries participating in the HALE study have experienced quite similar demographic changes with respect to the average life expectancy at the age of 60. Between years 1991 and 1998, the mean number of years still to be lived by a person who has reached 60 increased by 0.6 (Denmark)–1.2 (Finland, Portugal) years in men and by 0.2 (Denmark)–1.2 (Switzerland) years in men to 21.9(Denmark)–25.2 (France) years in women. 

Self reporting is another possible source of bias. In the old-old, self reported measures may give a more optimistic view of the physical abilities than performance based measures. Some studies have shown a strong correlation between subjective and objective measures of physical functioning whereas others have found the association to be much lower. However, subjective and objective measures capture physical abilities differently: the performance indices may be seen as indicators of functional limitations at a given time point whereas self reported ADL reflects experienced disability over at least a slightly longer period of time and, thus, the ability of a person to live independently in their own home, whether relying on various aids or equipment or without any aid.

In this study significant confounding attributable to methodological differences (definitions and wording of questions, translation of the questionnaire) is unlikely because we assessed physical functioning by means of a standardised questionnaire and only ADL items identical in both studies were included in the analyses. Furthermore, the

*Derived from models including age in years (as two terms, age and age²) and region (1 = north, 2 = south) (all models), study (1 = SENECA, 2 = FINE), and follow up (1–3).
translational processes were performed in a similar way in both studies. We also used multivariate models to adjust for study (FINE compared with SENECA) to avoid bias attributable to differences between the two study populations.

Older adults' physical functioning may either decline or improve over time. Therefore, we used a statistical method that accounts for changes in both directions within and between subjects. To our knowledge, ours is the first study to report on disability prevalence trends in aged Europeans in a longitudinal setting. Previous comparative cross national studies have been cross sectional.

Our finding is in line with existing longitudinal studies based on national samples. A prospective study in a younger population of Finnish men and women showed results congruent with those of ours. This study measured self reported functioning in mobility tasks and found gradual improvement in functioning with succeeding birth cohorts. Another Finnish population study failed to find a significant cohort effect in a population of men and women aged 75+ although the general trend was towards slightly better functioning in later birth cohorts. A secular trend toward a less disabled and healthier population has also been reported in US populations aged 65+ by Manton et al and 55 to 70 years by Alilla et al. Manton et al further showed that the reduction in disability over time, which had already been seen a decade earlier, had accelerated from the 1980s to the 1990s.

Interestingly, a Canadian study based on earlier samples reported contradicting results suggesting that later generations were less healthy than earlier ones. It is possible that populations experience a shift toward healthier aging at different phase and at different points in time. Furthermore, it has been suggested that as a country becomes more developed there may be an increase in the prevalence of disability among the elderly population. It is a limitation of this study that the economic development of the participating countries could not be assessed.

The finding that physical functioning of elderly Europeans has improved over time is important from the perspective of health policy making. It implies that the need for social and medical services may not increase in phase with aging of the populations. European countries will experience an increase in absolute numbers of elderly people and thus also the absolute numbers of people with functional impairment and disability are likely to increase. However, as later birth cohorts maintain functional abilities better than earlier ones, the proportions of older people with disability will decrease.

In view of earlier studies we suggest that culturally determined lifestyle related or socioeconomic factors may explain the regional variation in disability prevalence trends seen in this study. The importance of socioeconomic inequalities in health that exist also among older adults has been shown to vary between cultures and socioeconomic groups may adopt health related practices differently. Health related lifestyle and health behaviour are also affected by cultural traditions. Healthy lifestyle in general has been shown to delay age related deterioration of health.

While the relation between age and chronic disease with functional impairment is well reported, comparatively little is known about the role of other possibly modifiable factors in dynamics of functioning. Existing data have proved that comparatively high proportions of elderly people maintain their functional capacity or even experience recovery of impaired functioning. Policy makers and health professionals need concrete tools when planning actions aimed at preventing or reverting functional decline both at population and individual level. Future research should therefore focus on identifying factors that help promote physical functioning in older adults.
