Air pollution and mortality in Barcelona

Jordi Sunyer, Jordi Castellsagué, Marc Sáez, Aurelio Tobias, Josep M Antó

Abstract

Study objectives – Studies conducted in Barcelona reported a short term relation between daily air pollutant values and emergency department admissions for exacerbation of chronic obstructive pulmonary diseases and asthma. Air pollution in Barcelona is mainly generated by vehicle exhaust and is below the World Health Organization air quality guidelines. The acute relation between air pollution and mortality was assessed.

Design – Daily variations in total mortality, mortality in subjects older than 70 years, and cardiovascular and respiratory mortality were related with daily variations in air pollutants for the period 1985–91, using autoregressive Poisson regression models that allow to control for temperature, relative humidity and variables handling temporal and autoregressive patterns.

Main results – Black smoke and sulphur dioxide (SO₂) were related to total mortality (relative risks (RR) for 100 µg/m³ = 1.07 and 1.13 respectively), elderly mortality (RR=1.06 and 1.13), cardiovascular mortality (RR=1.09 and 1.14), and respiratory mortality (RR=1.10 and 1.13); all the associations being statistically significant, except for respiratory mortality (p=0.07). The association between SO₂ and respiratory mortality was stronger in summer (1.24, p<0.01) than in winter (1.08, p>0.1). Oxidant pollutants (nitrogen dioxide and ozone) were positively related with elderly mortality (RR= 1.05 and 1.09, respectively) and cardiovascular mortality (RR=1.07 and 1.09) during the summer (p<0.05), but not during the winter.

Conclusions – Current air pollutant levels were related to mortality in Barcelona. These results were consistent with similar studies in other cities and coherent with previous studies with emergency room admissions in Barcelona.

(*J Epidemiol Comm Health* 1996;50(Suppl 1):S76–S80)

Barcelona offers a useful environmental scenario in which to study air pollution health effects. Barcelona is mainly polluted by vehicle exhausts and the climate is mild. Levels of black smoke (BS), particles, and nitrogen dioxide (NO₂) are in the highest range for western cities participating in the APHEA project,¹ although they are within the World Health Organization air quality guidelines.² A recent chemical analysis of particles in the air in Barcelona showed that vehicle exhausts accounts for 35% of the

total particulate amount whereas industry and heat emissions contribute only 1%.³ Some 50% of the particles were attributed to soil dust.³ Correlation between temperature and pollutants is relatively low, particularly in summer,⁴ facilitating the adjustment for temperature.

Studies conducted in Barcelona reported a short term relation between air pollution levels and the number of emergency department admissions for exacerbation of chronic obstructive pulmonary diseases⁴⁻⁵ and asthma.⁶ Sulphur dioxide (SO₂) and BS were the pollutants related to chronic obstructive pulmonary disease,⁵ and although it is a complex correlation, an independent association for both pollutants was found.⁵ BS and NO₂ were the pollutants related to asthma.⁶ We studied the coherence between our previous findings on emergency department admissions and the present study on mortality, and the consistency with studies on mortality carried out in other cities representing a wide range of environments. In addition, we used the mortality data to enable us to extend the series of data used for emergencies. In particular, the objective of the present paper was to assess the relation between air pollutants and mortality, and to identify the pollutants and mortality causes involved.

Methods

The procedures followed in this study were those agreed for the APHEA protocol.¹ Daily variations in mortality were related to daily variation in air pollutants using regression methods. Different markers of mortality and air pollution were assessed and are described below, as well as the variables used to control the possible confounding effect due to meteorology and temporal effects. Of particular importance is the assessment of different associations related to season, since urban atmospheres differed qualitatively by season,⁷ as well as the confounder variables^{3,6} and their interactions with the pollutants.

HEALTH DATA

Daily deaths for the period 1985–91 were supplied by the regional mortality register, whose completeness and quality have been proved to be good.⁸ Total mortality, total mortality for subjects older than 70 years, cardiovascular causes (ICD9 codes 390 to 459), and respiratory causes (ICD9 460 to 519) were assessed.

Daily total mortality (1985–1991) ordered by calendar, residual plot after adjustment for confounding variables, and final residual plot after inclusion of pollutants.

AIR POLLUTION DATA

The 24 hour average levels (collected from 8 am one day to 8 am the next day) of BS (OECD method) were computed as the arithmetic mean of the measurements provided by seven manual samplers placed around the city. In previous reports we used a larger network, but this was reduced in 1990. Only one of the samplers gave missing values for more than 5% of days. SO₂ (fluorescence method), NO₂ (chemiluminescence method), and ozone (O₃) (chemiluminescence method) were averaged from three automatic stations from 1985. Data from the automatic samplers for the year 1985 were not considered because of quality problems at the beginning of the monitoring. Each station represented a different type of urban pollution (industrial, residential, and residential with high traffic). For all pollutants, missing observations for specific samplers (19% to 25%) were replaced by the city's average value, following the procedure stated by APHEA.¹ Daily information on average temperature, relative humidity, and dew point temperature were collected by the National Meteorological Institute from a station at the airport (8 km far from the city).

ANALYSIS

The relation between pollutants and mortality was assessed using separate regression models for each pollutant and each different category of mortality. Three consecutive steps were followed according to the procedure stated by APHEA as follows:

- The parametrisation of a linear model on log transformed mortality, using least squares method to control for temporal variations, meteorology, and other confounding variables (for

example, influenza epidemics) to obtain a residual plot without any temporal pattern;

- The introduction of pollutants at different lags in the previous best fitted models;
- The estimation of an autoregressive Poisson model using maximum likelihood estimations including all the variables selected in the previous steps.

In addition, interactions between pollutants and season were assessed.

A model for each log transformed mortality indicator was fitted. All models fitted included a linear and a quadratic term for trend and a dummy variable for each year to control for long term trends, a sinusoidal term up to the fourth order to control for season, a dummy variable for each day of the week and for holidays, a linear and quadratic transformation of humidity and temperature at current day values, a dummy variable for influenza epidemics, and interactions between years and sinusoidal terms to completely adjust for seasonality. Dummy variables for high humidity or very hot or cold days and interaction between these variables were included in the models but were avoided in the end since they did not improve the goodness of fit of the models. A total of 72 variables was included in the models.

Pollutants, temperature, and humidity were assessed up to a third lag, except for O₃, which was assessed up to a fifth lag. Logistic and quadratic transformations of the pollutants were assessed, but for all of them the untransformed variable showed the best goodness of fit. The final Poisson regression models were fitted including up to four autoregressive parameters. Modifications of the effect in relation to season were assessed by including in the final models an interaction parameter between the air pollutant and a dummy variable for

Table 1 Daily number of deaths and air pollutant levels (in µg/m³) in Barcelona in relation to season, during the period 1985–91

Variable (no of d)	Winter* Median (range)	Summer* Median (range)
Total mortality (2557)	48 (22–98)	43 (18–85)
Total mortality in those >70 y (2557)	33 (13–68)	29 (11–66)
Cardiovascular mortality (2557)	21 (7–47)	18 (5–44)
Respiratory mortality (2557)	5 (1–16)	4 (1–15)
Temperature (2557)	11.3 (–2.0–35.5)	19.7 (0–27.9)
Black smoke–24 h average (2464)	49.7 (11.4–66.7)	35 (10.6–125.6)
SO ₂ –24 h average (1825)	46 (2.2–160)	36.4 (5.4–116.5)
NO ₂ –maximum daily value/h (2164)	88.4 (8.3–339.2)	97.3 (8.0–336.4)
O ₃ –maximum daily value/h (2164)	55.2 (7–189.2)	86.5 (9.5–283.5)

* Winter = October to March, and summer = April to September.

Table 2 Correlation coefficients for 24 hour averages of black smoke (BS) and sulphur dioxide (SO₂) and one hour maximum value of nitrogen dioxide (NO₂) and ozone (O₃), and temperature

	BS	SO ₂	NO ₂	O ₃	Temperature
BS	1				
SO ₂	0.634	1			
NO ₂	0.290	0.262	1		
O ₃	–0.334	0.181	0.295	1	
Temperature	–0.297	–0.218	–0.011	0.415	1

semester (from April to September, and from October to March). The figure shows the residuals of total mortality which exemplify the process carried out with all the studied associations. Goodness of fit was assessed by visual inspection of the residual plots by an external statistician in the coordinating centre, improvement in the deviance, and the Durbin-Watson test for autocorrelation. SAS procedures were used for the analyses.

Results

Table 1 presents the distribution and seasonal variation of the mortality and air pollutant data. Mortality, SO₂, and BS showed higher values in the winter period, whereas O₃ showed higher values during the summer period (p<0.05). Differences in NO₂ in relation to season were not statistically significant. Table 2 shows the correlation between pollutants and between pollutants and temperature. BS and SO₂ were highly correlated, whereas correlations with oxidants and between oxidants were low. O₃ presented the highest correlation with temperature and NO₂ the lowest; the correlation between BS and SO₂ and temperature was relatively small.

Table 3 shows the relation between the different pollutants and the different mortality groups. BS and SO₂ were related to total mortality in the elderly, and cardiovascular and respiratory mortality, although with the latter at the limit of the statistical significance (p<0.1). The associations with BS did not vary in relation to season whereas the association between SO₂ and respiratory mortality was higher in the summer than the winter (although differences in relation to season were not statistically significant (p>0.1)). Similarly, NO₂ and O₃ were related to total, elderly, cardiovascular, and respiratory mortality, although the association with respiratory mortality was not statistically significant. The relation between oxidant pollutants and cardiovascular mortality varied by season; it was positive and significant in the summer, but negative and non-significant in the winter. For BS, SO₂ and O₃ the association with specific mortality was stronger than with total mortality (although differences were not statistically significant, p>0.1). Most of the associations were found with current and one day lags, except for BS and O₃ with respiratory mortality, which showed positive associations from the third and fifth lag day, respectively. Cumulative measures of pollutants for the three previous days did not improve the estimations with single day air pollutant values.

In order to assess whether the extensive parametrisation of the models affected the inferences and the stability of the associations obtained, we present in table 4 the changes in the coefficients of BS and SO₂ in relation to total mortality after the consecutive inclusion of parameters in the models. The estimation of BS was found to be more sensitive to the parameters included than that for SO₂. In particular, the inferences for BS would differ if the last step in the inclusion of variables was not produced.

Discussion

We found a significant association between BS and SO₂ and total and specific mortality for cardiovascular and respiratory diseases. The associations between SO₂ and mortality groups were stronger than those with particles, in par-

ticular the association with respiratory causes. These results agree with previous reports in Barcelona.^{4,5} The magnitude of the associations found for both pollutants was in the upper range of those reported.^{9,10}

A second finding was the association of the oxidant pollutants (NO₂ and O₃) with mortality, particularly in the elderly and those with cardiovascular causes. Only some reports from Los Angeles (USA)¹¹ have previously found an association between total and cardiovascular mortality and oxidants. Los Angeles and Barcelona share similar climates, geography, sources of pollution, and levels of pollutants. On the other hand, the relation between NO₂ and respiratory mortality was the lowest observed and non-significant, coinciding with non-significant associations found in previous reports on emergency department admissions for chronic obstructive pulmonary disease in Barcelona.⁴ Although previous studies have found a positive association between NO₂ and asthma emergencies in Barcelona,⁶ asthma mortality has a small impact in the overall respiratory mortality, and no relation was expected between NO₂ and mortality for all respiratory causes. Similarly, previous studies showed an association between O₃ and hospital admissions for asthma in Vancouver,¹² but the present association with respiratory mortality was observed only from the fifth lag day and it was not statistically significant.

The biological explanation for these findings seems coherent for SO₂, for which a stronger association was observed for respiratory causes and in the elderly, consistent with the biological mechanisms of this pollutant.¹³ However, for BS the associations with cardiovascular and respiratory mortality were similar, and for NO₂ and O₃ the association with cardiovascular mortality was higher, but the explanations for a cardiovascular effect are unknown. A confounding effect due to CO should be considered, since it is a pollutant generated by motor vehicles that is firmly related to heart diseases.¹⁴ Recently, Seaton *et al*¹⁵ proposed a biological hypothesis for the relation between particles and cardiovascular deaths (that is, particles in susceptible subjects would increase the viscosity and coagulability of the blood, increasing the likelihood of a heart attack). This theory links with the evidence of a relationship between smoking and increases in white blood cells,¹⁶ fibrinogen and viscosity,¹⁷ which partly explained the cardiovascular risk of smoking.^{16,17}

Why SO₂ and oxidants showed a stronger relation with respiratory and cardiovascular mortality, respectively, during summer than

winter is unknown. During winter people are less exposed to outdoor air than in summer which could lead to a higher misclassification in the exposure measurement. Another explanation is that competing causes of death (that is, low temperature, respiratory infections) had a much lower impact during summer. It is also possible that the toxicity of the pollution mixture varied by season and was more toxic during summer, although the concentration of volatile compounds (including some irritants) in summer is 10 times lower than in winter.⁷ Summer probably offers a much better scenario than winter in which to study the health effects of air pollution in places like Barcelona.

BS actually measures fine black particles from heating with coal. In Barcelona, most heating is by methane gas which does not release black particles. To what extent BS is a surrogate for respiratory particles (including non-black particles) is unknown. Misclassification due to error of measurement of the actual exposure is a common problem in studying air pollution epidemiology and probably leads to an underestimation of the true associations.¹⁸ How reliable is the specific mortality? In Barcelona, cardiovascular and respiratory deaths showed an agreement of 78%,⁸ which suggests a degree of misclassification for these causes that may bias the present estimations, probably towards the null hypothesis.

The confounding effect of temperature is a keystone in the analysis of daily variations in mortality and pollution. A study in The Netherlands¹⁹ showed the disappearance of the association due to SO₂ after an appropriate adjustment for temperature. In the present analysis a great effort has been made to adjust for different forms and functions of temperature and dew point, without any changes in the pollutant coefficients. In addition, we carried out a different way of modelling temperature and humidity²⁰ and the final inferences of the adjusted associations for SO₂ and BS were identical to those presented here. The latter analysis²⁰ was carried out with a different statistical methodology, using ARIMA methods to control for seasonality and extreme meteorological days, and the final inferences were the same, suggesting that present results were not spurious associations due to the statistical methods.

The search for individual pollutants related to health effects faces the quite impossible task of measuring complex exposures such as urban pollution. Conversely, the understanding of individual associations leads to biological explanations and has a direct link with the public health preventive strategy of setting standards. In the last decade, the principal pollutant of interest in air pollution epidemiology has been particles.^{9,10} However, we have repeatedly found that SO₂ has a much stronger and consistent association with the health indicator (that is, an association with respiratory mortality that is stronger than that with total mortality, opposite to the association with BS and no modification of the estimates in the sensi-

tivity analyses, at variance with BS). To what extent SO₂ is a marker of fine particles⁹ or "toxic" by itself deserves toxicological studies and comparisons with epidemiological studies conducted in different environments.

The present positive associations coincide with most of the positive associations from reports studying the acute temporal relation between mortality and urban air pollution, and also with our previous studies on emergency department admissions. The reproducibility of positive associations between air pollutants and mortality in different places differs with the lack of clear biological explanations for how a small increase in some pollutants may cause death.
