Background: Although adult reported childhood socioeconomic position has been related to health outcomes in many studies, little is known about the validity of such distantly recalled information. This study evaluated the validity of adults' reports of childhood paternal social class.

Methods: Data are drawn from the Aberdeen children of the 1950s study, a cohort of 12 150 people born in Aberdeen (Scotland) who took part in a school based survey in 1962. In this survey, two indices of early life socioeconomic position were collected: occupational social class at birth (abstracted from maternity records) and occupational social class in childhood (reported during the 1962 survey by the study participants). Between 2000 and 2003, a questionnaire was mailed to traced middle aged cohort members in which inquiries were made about their fathers' occupation when they were aged 12 years. The level of agreement between these reports and prospectively collected data on occupational social class was assessed.

Results: In total, 7183 (63.7%) persons responded to the mid-life questionnaire. Agreement was moderate between social class of father recalled in adulthood and that measured in early life (κ statistics were 0.47 for social class measured at birth, and 0.56 for social class reported by the child). The relation of occupational social class to birth weight and childhood intelligence was in the expected directions, although weaker for adults' reports in comparison with prospectively gathered data.

Conclusions: In studies of adult disease aetiology, associations between childhood social class based on adult recall of parental occupation and health outcomes are likely to underestimate real effects.

In the past decade there has been a re-emergence of interest in the early life origins of adult disease, particularly coronary heart disease (CHD).^{1–4} One of the most commonly examined social determinants is childhood socioeconomic position,⁵ typically indexed by the occupational social class of the father during the study participants' early life. An association with later life CHD events^{5–6} and its risk factors^{7–9} has been reported, such that the most unfavourable levels are apparent in adults from the most disadvantaged socioeconomic backgrounds.

Given the scarcity of prospective studies that offer extended follow up of children into later life, out of necessity most investigators examining the aetiological role of childhood social conditions have done so in cohorts of middle aged persons where this information is recalled from as much as six decades earlier.^{8–12} This practice raises important concerns about the accuracy of such data, not only when it is the exposure of interest but also when assessing its potential confounding effects.^{13–14}

While investigators have reported on the accuracy of children's or young persons' contemporaneous recall of their parents' occupation^{15–16} and adults' reports of their own occupational history up to 40 years in the past,¹⁷ we are aware of only two studies that have attempted to examine the accuracy of adults' recall of their childhood social class. In one,¹⁸ the degree of corroboration between adult twins' reports of parental occupation was assessed but no comparison was made with independently collected information in childhood such as that available in historical records. In another,¹⁹ although levels of agreement between archived records and adult self report appeared high, the analyses were based on less than 60 subjects. A further shortcoming of these studies, and one that often applies to validation studies in general, is that no estimate was provided of the probable effects of any misclassification.

The children of the 1950s study is a large cohort of men and women who participated in a school based survey in Aberdeen, Scotland in 1962. Data on childhood socioeconomic position and other characteristics were collected at the time of their birth (mother's reports of husband's occupation; birth weight) and during the school survey (study participants' report of father's occupation; psychometric intelligence).²⁰ Recently, a questionnaire was mailed to surviving cohort members, now middle aged, in which inquiries were made regarding the respondents' childhood social circumstances, including their father's occupation.

We are therefore able to: (1) quantify the accuracy of distantly recalled occupational social class by relating paternal social class as ascertained from both historical records (at birth) and children's reports (during original survey), on the one hand, with childhood social class reported in middle age, on the other; (2) assess the likely effect of any misclassification by relating both child and adult recalled occupational social class to outcome variables known to be associated with contemporaneously gathered data on childhood social circumstances: birth weight^{21–22} and psychometric intelligence.²³

METHODS

Study participants

The Aberdeen children of the 1950s study is a cohort of 12 150 children born in Aberdeen, Scotland, between 1950 and 1956 who took part in a school based survey beginning in 1962.^{20–24–25} During this time, comprehensive information was also abstracted from the Aberdeen Maternity and Neonatal Databank (AMND) about the course of their mother's pregnancy and the children's physical characteristics at birth.²⁰ In 1999 this study was revitalised with surviving cohort members traced and mailed a questionnaire between

Table 1 Study participants with occupational social class data in childhood and adulthood

Year of data collection	Reference period	Subjects with data*	Manual†	Non-manual
Infancy (1950–56)	Birth	11469 (94.4)	8971 (78.2)	2498 (21.8)
Childhood (1962)	6–12 years	11233 (92.5)	8127 (72.4)	3106 (27.7)
Adulthood (2000–03)	12 year	6594 (54.3)	4742 (71.9)	1852 (28.1)

*Results are number (%). †Occupational social class dichotomised into manual (IIIM, IV, and V) and non-manual (I, II, IIINM) groups.

2000 and 2003 regarding health and health related factors.^{20–26}

Prospective assessment of early life social class

Occupational social class of the study participant's father was assessed at two time points in early life: birth and childhood. Social class at birth was based on the occupation of the participant's father, reported by the study participant's mother, and recorded in the AMND. The AMND records, established and maintained for analytical purposes by a team of experienced researchers, hold research-standard information.^{20–27} At the time of the school based survey (1962), the father's occupation was reported by each child. Studies of the accuracy of occupational social class reported simultaneously by child and parent suggest a high level of agreement.^{15–16} Data from both time points were classified into six categories according to schema resembling the 1950 registrar general's revision²⁸: I—professional; II—managerial; IIINM—non-manual, skilled non-manual; IIIM—manual, skilled manual; IV—manual, semi-skilled; and V—unskilled manual. As this is an occupational classification, data were not coded for children whose fathers were unemployed at either birth and/or when they were surveyed at school.

Retrospective assessment of early life social class

Using the procedures of the NHS Central Register, over 98% (n = 12 015) of the children of the 1950s cohort have been successfully traced. Between 2000 and 2003 we attempted to mail a questionnaire to 11 283 surviving study participants aged between about 44 and 52 years. In total, 7183 (63.7%) responded. Responders were more likely to be female,²⁰ have higher psychometric intelligence scores as children,²⁶ and to come from more affluent backgrounds in childhood.

Questionnaire respondents were asked to consider the period when they were 12 years of age. This epoch was chosen because it was close to the midpoint of childhood, and also the time at which most study participants would have transferred from junior to senior school, so representing a memorable period in their lives. Participants provided information on their father's occupation by replying to inquiries regarding his job title and job description that included an item with pre-defined categories: manager or

foreman/supervisor; an employee (other than manager; foreman/supervisor); self employed with employees; self employed/freelance without employees. These data were converted to a standard occupational classification and then the registrar general's 1961 schema²⁹ (the earliest revision available electronically) using CASOC software.³⁰

Assessment of other characteristics

During the study period in the early 1960s, educational authorities in Scotland routinely measured intelligence as a means of determining the secondary school destination of each child (that is, junior or senior secondary). Tests of psychometric intelligence were given to school children at 7, 9, and 11 years of age, and these scores were extracted from school records at the time of the schools based survey.²⁰ In our analyses we used the test results at age 7 as our measure of childhood psychometric intelligence as this provides an indication of mental ability largely unaffected by formal education. The tests used were the Moray House picture intelligence tests number 1 or 2, which was given within six months of the study participants' 7th birthday.²⁰ The test is based on line drawings and examines a child's perception and understanding of pictorial differences. Although, to our knowledge, the Moray House test has not been validated against other childhood IQ tests, in this cohort it shows the expected associations with early life social conditions,²⁰ fetal growth,³¹ and adult mortality experience.²⁶ Data on birth weight, measured directly by midwives, were abstracted from the AMND. Again, in this population, birth weight shows the expected inverse relations with childhood visual acuity³² and adult cardiovascular disease risk.³³

Statistical analyses

Analyses were conducted for the full range of social class categories. The agreement between each measure of occupational social class was estimated visually by presenting cross tabulations and statistically by computing percentage agreement and weighted κ statistics. Weighted κ statistics were used to account for the greater disagreement between categories that are further apart than those that are close together on an ordinal scale.³⁴ Linear weights were calculated as $w_i = 1 - (i/5)$, where w_i is the weight given for a distance of

Table 2 Agreement between social class data based on birth records and adult reports

		Birth records						Total
		I	II	III NM†	III M‡	IV	V	
Adult reports	I	136	69	10	55	3	2	275
	II	41	340	214	271	41	34	941
	IIINM	6	82	280	132	40	29	569
	IIIM	6	53	181	2099	401	380	3120
	IV	2	24	125	357	348	265	1121
	V	0	1	9	60	53	215	338
Total		191	569	819	2974	886	925	6364*

*Level agreement = 54.0%; weighted κ statistic = 0.47, $p < 0.001$. †non-manual; ‡manual. Occupational social class was categorised as follows: I (highest)—professional; II—managerial; IIINM—non-manual, skilled non-manual; IIIM—manual, skilled manual; IV—manual, semi-skilled; and V (lowest)—unskilled manual.

Figure 2 Mean difference (95% confidence interval) in psychometric intelligence comparing subjects in manual* childhood occupational social class with those in non-manual (n = 5945). *Occupational social class dichotomised into manual (IIIM, IV, and V) and non-manual (I, II, IIINM).

by age at measurement. Levels of agreement were essentially the same whether the child was <9 years or ≥9 years at the time of the childhood survey.

We examined if there were sex differentials in the accuracy of reporting of these data by stratifying our analyses by sex (data not shown). There was essentially none: the κ statistic for social class at birth compared with adult recall was 0.46 (women) and 0.48 (men), while for childhood social class compared with adult recall the results were identical ($\kappa = 0.56$ for men and women). These κ statistics, in keeping with those reported in tables 2 and 3, were significant ($p < 0.001$).

We compared the difference in mean birth weight (fig 1) and childhood psychometric intelligence (fig 2) between high socioeconomic position and low for each measure of occupational social class. These analyses were conducted on people with complete data on all three measurements of occupational social class and the outcomes (n = 6113 with birth weight as the outcome, and n = 5945 with psychometric intelligence as the outcome). The mean (SD) birth weight among women was 3233 (503 g), and among men 3361 (515 g); the corresponding results for IQ were 107.4 (16.5) and 106.7 (16.3). Negative mean differences—those to the left hand side of the vertical line denoting no effect (that is, zero mean difference)—indicate a lower birth weight or IQ in those from manual compared with non-manual social classes. The point estimates in both figures suggest weaker associations of IQ and birth weight with adult retrospective report of social class in comparison with either prospectively collected early life measurement. While there was no statistical evidence of heterogeneity in the effect of occupational social class on birth weight across the three measures ($p = 0.4$), when IQ was the outcome of interest there was a noticeable weaker association for adult reported childhood social class than for either prospective social class measurement (p value for heterogeneity = 0.006).

DISCUSSION

In the largest study to date to examine the issue, middle aged adults' recall of early life social class showed moderate agreement with social class data collected prospectively up to five decades earlier, either from birth records or from reports made in childhood. Disagreements were generally ascribed to adults reporting a higher (more favourable) occupational social class to that recorded in early life. To quantify the potential implications of any misclassification we related the occupational social class data to birth weight and childhood intelligence, which have repeatedly been shown to be associated with early life socioeconomic factors.^{21–23} Using each measure of occupational social class resulted in the same conclusion: the lowest levels of birth weight and IQ were found in the most socially disadvantaged groups.

Comparison with other studies

Our results are in broad agreement with two previous studies addressing the validity of distant recall of childhood socioeconomic position, both of which used data on occupational social class. In the only directly comparable investigation, Berney and Blane¹⁹ reported an exact match of 66% between older adults' reports of their father's occupation in their youth and historical data recorded from 50 years earlier. In this study, the sample size was small (n = 57) and follow up data were based on an intensive interview schedule, an approach that is not practical in large scale, population based studies. However, the similarity in levels of agreement between this and our study, suggest that simple questionnaire inquiries elicit data that are as valid as those obtained from detailed interviews. In the only other study,¹⁸ the degree of corroboration between adult female twins' reports of fathers' occupation was also high but, as previously indicated, no comparison with historical records was made. In neither of these studies did the investigators attempt to examine the potential implications of any misclassification as we have done.

An alternative assessment of the effect of any misclassification could be provided by using a dataset that holds information on both retrospectively and prospectively collected childhood social class and relating this information to an outcome that has been shown to be socioeconomically patterned, such as CHD. It will be some years before this cohort has accumulated sufficient CHD events to facilitate such an analysis. In the meantime, some evidence for a differential effect of childhood social class reported in adulthood and that prospectively gathered can be found by

What this paper adds

- Although adult reported childhood socioeconomic position has been related to health outcomes in many studies, very little is known about the validity of such distantly recalled information.
- In this study we found moderate agreement between social class of father recalled in adulthood and that measured prospectively in childhood.
- The relation of childhood IQ and, to a lesser extent, birth weight, was weaker with adult recalled social class than prospectively collected childhood social class data.
- In studies of adult disease aetiology, associations with childhood social class based on adult recall of parental occupation are likely to underestimate any real effects.

comparing results across studies. In a recent review by Lynch and Davey Smith⁵—necessarily narrative because of the problems of statistically aggregating results from observational studies in a meta-analysis—the authors found that, in studies in which childhood social circumstances were measured prospectively, the relation with CHD was generally stronger than those in which this exposure were recalled in adulthood.

Misclassification of social class

While misclassification between childhood social class ascertained contemporaneously and recalled in adulthood may be ascribed to inaccuracies in recalling such information from up to five decades earlier, at least three further explanations exist. Firstly, in the original survey dataset made available to us, the occupational data from the schools survey and birth records had been pre-coded to a schema resembling the registrar general's 1950 revision²⁸; the verbatim descriptions of occupation, from which these classifications were derived, were not available. In coding parental occupation from data collected in mid-life, the earliest schema available to us for electronic transformation was the 1961 revision.²⁹ It is possible, therefore, that some of the disagreement between childhood and adult ascertained childhood is attributable to these coding differences.

Secondly, the periods in which measurement of early life social class was made herein varied across indices. In the follow up questionnaire, carried out when the study participants were middle aged, respondents were asked to focus on the period when they were 12 years of age, while the prospective data were collected at birth (from routine birth records) and when the study participants were between 6 and 12 years of age (reported during the 1962 schools survey). We examined if the age of the school child during participation in the survey modified the level of agreement between reports from this period and those in middle age. On stratifying age at survey into two groups (<9 years and ≥9 years), the weighted κ statistic was essentially unchanged, suggesting age difference does not explain the misclassification. A third and related point is that there was upwards socioeconomic mobility in the city of Aberdeen between the 1950s—during which the study participants were born and experienced their early childhood—and the 1960s when they would be aged 12. Two findings mitigate against upwards social mobility as a likely explanation for the lack of agreement. The economic boom in Aberdeen after the discovery of North Sea oil did not occur until the mid-1970s.²⁰ Furthermore, our comparison of birth with childhood social classes suggested that there was, in fact, a moderate downward shift in socioeconomic position over this period.

Study strengths and limitations

The sample size in this study is an order of magnitude higher than others that have examined the same issue; moreover, this is the first to attempt to measure any possible impact of misclassification. While this report therefore represents a unique contribution, various weaknesses should be considered. It is plausible that in study participants whose fathers were particularly socially mobile, recall may be less accurate. We do not, however, have employment histories of these men to enable us to examine this issue. It is also possible that, because of differing cultural contexts, the level of occupational misclassification may vary from one country to another. It may be of value, therefore, to repeat this study in other populations. Additionally, herein, adult reported childhood occupational social class is, by definition, only available for study survivors who responded to a questionnaire survey. However, this reflects the very situation in

which adults' recall of childhood circumstances will be used in studies of disease aetiology.

Finally, the response to our mailed questionnaire was moderate (64%), with non-responders more likely to be from disadvantaged backgrounds. This response proportion is similar to that in comparable follow up surveys conducted in the 1946³⁶ and 1958³⁷ birth cohort studies. When we related reports of childhood social class from the questionnaire to data collected in early life, where disagreement occurred, it tended to be adults placing their fathers' occupation into a higher socioeconomic position compared with their reports in childhood. Had the response proportion been greater, with a higher representation of study participants from poorer childhood social backgrounds, it is plausible therefore that the level of agreement may have been lower and the association with birth weight and childhood intelligence weaker.

Conclusion

In the largest study to date to examine the issue, there were moderate levels of agreement between prospectively recorded early life social class and adult reports of their father's social class made up to five decades later. Furthermore, where discordance occurred, adults tended to exaggerate their father's status compared with contemporary measures. Associations of the measures of social class with birth weight and childhood intelligence were in the expected directions, and were generally weaker for adult reported measures of childhood social class than for contemporaneous indicators.

We suggest that, where possible, prospectively gathered measures of early life occupational social class should be used in aetiological studies. Where these data are unavailable, associations of childhood social class based on middle aged adults' recall of parental occupation and adult health outcomes are likely to underestimate the real associations.

ACKNOWLEDGEMENTS

We are grateful to Raymond Illsley for providing us with the data from the Aberdeen child development survey and for his advice about the study. Graeme Ford had a crucial role in identifying individual cohort members and in helping us initiate the process of revitalisation. Doris Campbell, George Davey Smith, Marion Hall, Bianca De Stavola, Susan Morton, David Godden, Di Kuh, Glyn Lewis, and Viveca Östberg collaborated in revitalising the cohort. Margaret Beveridge assisted with the management of the study. We also thank staff at the ISD (Edinburgh), GRO (Scotland), and NHSCR (Southport) for their substantial contributions and John Lemon who undertook the linkage to the AMND. Finally, we are particularly grateful to the study participants who responded to a mailed questionnaire some 40 years after the original survey was completed.

AUTHOR CONTRIBUTIONS

S Macintyre, G D Batty, and D A Lawlor developed the idea for this paper. D A Lawlor undertook all the statistical analysis. D A Lawlor and G D Batty wrote the first draft of the paper. G D Batty coordinated further revisions to which D A Lawlor, S Macintyre, H Clark, and D A Leon all contributed.
