Evaluation of patients’ assessment of day hospital care

H. PEACH AND M. S. PATHY
From the University Hospital of Wales, Cardiff

SUMMARY The method of linear analogue self-assessment (LASA) was used to quantify the views concerning day care which were held by patients attending a geriatric day hospital. The results suggest that day hospitals are an acceptable form of care for the elderly.

Although during the past 18 years there has been a steady increase in the number of geriatric day hospitals in the UK, the attitude of the patients to day hospital care has been largely ignored. The few measurements of the success of day hospitals have been objective—such as, ultimate outcome for the patients (Woodford-Williams et al., 1962; Blake, 1968; Brocklehurst, 1970; Millard and Martin, unpublished). To try to find out the patients’ views on day hospital care the technique of LASA was introduced at the St David’s Day Hospital, Cardiff.

Patients and methods

For this study 15 questions were used covering most aspects of day hospital care (Table 1). For each question a 5 cm or 10 cm line was drawn and the ends of the line were labelled with words descriptive of the extremes of the response. The patient was asked to mark the line at the point most appropriate to her feelings at that moment. The distance in cm along the line to this mark (questions 4, 6-8, 10, 12, 14, 15) or from the centre of the line to mark (questions 1-3, 5, 9, 11, 13) gave a score out of 5. The questions were read to the patients by two lay persons who were not involved in the day hospital but who had extensive experience of interviewing patients. Patients attending the day hospital for the first time were interviewed at the end of the first month after their admission.

To assess the reliability of the technique a sample of patients completed the questionnaire with each of the interviewers separately in the same week, and a further sample completed the questionnaire alone and again with an interviewer in the same week.

Results

Fifty-one patients were used in the study of whom 19...
The mean age of the men was 75 years (range 65-83) and that of the women 76 years (range 66-88). Most of the patients were brought to the day hospital by ambulance, only three using private transport. All but eight patients, seven women and one man, received physical treatment. All patients received medical and nursing care and in 14 of the subjects, five men and nine women, there was an element of social care.

Correlation between the patients' scores obtained by the two interviewers in the replicated sample was good (r = 0.85). However, correlation between the patients' scores obtained with and without the interviewer present was poor.

The mean score for each of the 15 questions is shown in Table 2. The mean score for most of the questions was high. Both the men and the women were keen to attend a day hospital again if the need arose. However, there was a difference in the mean score for some of the questions between the men and the women. The men did not find the journey to and from the day hospital as enjoyable as did the women. Moreover the men were dissatisfied with the amount of time they spent at the day hospital each day (11 indicated it was too much, only eight indicated that it was about right) and did not find the time spent with the occupational therapists as helpful as did the women. The women on the other hand did not find the time spent with the doctor as helpful as did the men.

Discussion

Correlation between the patients' scores with and without the interviewers was poor as many of the patients who appeared to understand the instructions on the questionnaire failed to follow them when answering the questions by themselves. With the interviewers the LASA technique proved an easily quantifiable way for the patients to record their assessments of day hospital care. The good correlation between the scores obtained by the two interviewers proved it to be reliable.

The high scores given by the patients suggest that on the whole they found the day hospital a satisfactory form of care. Women more than men tend to have multiple conditions and this may be one reason why they found the medical care less beneficial. Fifty-three per cent of the women had three or more serious conditions compared with only 26% of the men. Much of the occupational therapy at St David's Day Hospital includes useful activities of greater appeal to women and the results were not unexpected.

We thank Mrs Jean Watson and Miss Sheri Watson for interviewing the patients and Miss A. R. McKelvie for typing the manuscript.
