A systematic review of the use of computers in the management of hypertension

Alan A Montgomery, Tom Fahey

Abstract

Study objective—To assess the effect of computers and computer-based clinical decision support systems on the management of hypertension.

Design—Systematic review of randomised controlled trials.

Setting—Ambulatory hypertension clinics, community-based health centres, and general practices.

Participants—11,962 patients enrolled in seven trials retrieved from a systematic search (electronic databases, contact with authors, reference lists; no restriction on language).

Main results—Individual trials report on a diverse population of patients (newly diagnosed or established hypertensive patients), interventions (computers used for case finding, recall and registration, feedback on quality of blood pressure control and prescribing information), and outcomes (administration, physician performance and blood pressure control). Four of five trials reported an improvement in patient administration using a computer. Two of three trials reported an improvement in physician performance using a computer. Two of six trials reported an improvement in blood pressure control in patients using a computer. However, positive findings in two trials should be regarded cautiously because of the potential effects of cluster randomisation.

Conclusions—It seems that computers have a favourable effect on the uptake and follow up of patients in hypertension management. The effect of computers on physician knowledge, recording of information, and blood pressure control in patients is less conclusive and further studies are required.

Methods

Inclusion criteria

We included randomised controlled trials of the use of computers and CDSSs that investigated any dimension of the administration or management of hypertension. A CDSS was defined as an active knowledge system that uses case specific advice. Two or more items of patient data to generate risk stratification based on absolute risk assessment has been incorporated into hypertension guidelines, and requires that blood pressure and other cardiovascular risk factors need to be considered and modified.

Computer use is very common in general practice and is likely to increase as computers become more sophisticated. Around 80% of general practices were computerised in 1993, and this was predicted to rise to 92% by 1997. Efficient case finding, registration, recall, and review are recognised as central to effective management of high blood pressure in the community. These tasks are all readily facilitated by computers. Computers can also help with the prescribing of antihypertensive treatment in terms of dose, interactions, and compliance.

The use of computer-based clinical decision support systems (CDSSs) is expanding and computers and CDSSs have been shown to improve the process and outcome of clinical care. In addition clinical guidelines, in either written or computerised format improve preventive and clinical care, and prescribing and support services. Computers have the potential to make risk stratification easier and more accessible to doctors and patients during the consultation. For all these reasons computers are likely to play a more important part in the detection, treatment, and follow up of hypertension in the community.

We decided to perform a systematic review of all randomised controlled trials that evaluated the use of computers in the detection and management of high blood pressure in either community or hospital-based ambulatory settings.

Study identification

We searched the computerised databases of the Cochrane Library (1997 Issue 3), Medline (1966–1997), BIDS science citation index (1981–1997), and EMBASE (Excerpta Medica, 1980–1997) using the recommended Cochrane search strategy including the following Medical Subject Heading (MESH)
Table 1: Summary of seven randomised controlled trials that examined the use of computers in the detection and management of high blood pressure (see Results for fuller description of outcomes assessed)

N/A ≠ not assessed.

Terms: “computers”, “microcomputers”, “computer assisted therapy”, “ambulatory care”, “information system”, “expert systems”, “hypertension”, “blood pressure”, “blood pressure determination”, and “mass screening”. We also did a citation search of previous reviews on the subject and of studies identified in the search, and wrote to all authors requesting information about unpublished trials, additional data, and clarification of data when necessary. The search included studies published in non-English language journals. We were interested in randomised controlled trials that allocated patients, GPs or practices to computer interventions according to a random or quasi-random schedule.

STUDY EVALUATION

The quality of each study was assessed independently by the two authors according to criteria outlined in the Cochrane Collaboration handbook. Each criterion—Selection bias, Performance bias, Attrition bias and Detection bias—was scored from 1 to 3, the highest score for an individual trial being 12. Differences in trial quality scores were resolved by discussion. Data were extracted independently before being collated. Trial outcomes were summarised into the three categories listed above. Because of diverse outcomes and a relatively small number of trials examining any particular outcome, no quantitative summary measures for the outcomes were possible, and a meta-analysis was not performed.

Results

TRIALS INCLUDED/EXCLUDED

Seven randomised controlled trials that evaluated the use of computers in the treatment of hypertension were identified (table 1). The outcomes that were measured were diverse, with most of the trials examining more than...
one outcome. Patient uptake/administration was evaluated in five trials, four of which reported improvement using a computer.17–19 21 Physician performance was evaluated in three trials, two of which reported improvement using a computer.18 22 Control of blood pressure was evaluated in six trials, two of which reported improvement using a computer.19 21 Three comparative studies that did not fulfil our criteria for inclusion in the review were identified.24–26 These studies used a matched control,24 before-after,25 or longitudinal design26 respectively and assessed a total of six outcomes.

A further 29 papers were identified that did not fulfil the inclusion criteria. These either (a) used a computer in some way in the treatment of hypertension in a non-randomised study, or (b) described the development of a number of different computer systems that assist in the management of patient data or offer the physician advice on how to treat hypertension. A list of these references is available from the authors on request.

QUALITY ASSESSMENT
All trials were of similar methodological quality, with none scoring more than eight according to Cochrane quality criteria (table 1). The k statistic of between-rater agreement was 0.24. All seven trials scored 1 on Selection bias (randomisation method not specified or little or no effort made) and 3 on Performance bias (no co-interventions permitted). All except one trial scored 1 on Attrition bias because of not reporting losses to follow up or achieving follow up of less than 80%. All except two trials scored 1 on Detection bias because of either subjective outcome measures or non-blinding of outcome assessors. Additionally, cluster randomisation (randomising by practice/family but analysing by patient)

Prescribing

Coe et al. found that computer generated treatment recommendations did not provide any advantage over normal physician care.

Drug prescribing patterns were similar in both groups, and slightly more patients in the computer group appeared to suffer side effects.

EFFECTS ON BLOOD PRESSURE CONTROL

Two studies reported a greater percentage of patients in the computer group having controlled blood pressure. Van den Hoogen reported that after 18 months, 70% (95% CI 68%, 72%) of patients in practices using a computerised hypertension monitoring system had a diastolic BP <95 mm Hg, compared with 56% (95% CI 49%, 63%) of patients in usual care practices. Barnett et al. found that at 12 months follow up 51% (95% CI 38%, 64%) of patients whose physicians received a computer generated
Computers have a favourable effect on the management of hypertension. The three outcome dimensions measured were patient administration, physician performance, and blood pressure control, with six of the seven trials examining more than one outcome. Patient uptake/administration was evaluated in five trials, four of which reported significant improvement using a computer. \(^{18-21}\) Physician performance was evaluated in three trials, two of which reported improvement using a computer. \(^{18-21}\) Control of blood pressure was evaluated in six trials, two of which reported improvement using a computer. \(^{18-21}\) However, positive findings from two of the trials should be regarded cautiously because the possible effects of cluster randomisation may have been responsible for the significant results found. If this was the case, the number of trials reporting improvement in each of the outcome measures would be: patient uptake/administration, two of five; physician performance, one of three; control of blood pressure, one of six.

Two previous reviews that examined the effects of computers on patient care were more positive in their findings. \(^{8}\) A systematic review of computer use in general practice reported that all 21 studies examining clinician performance demonstrated an improvement in outcome. \(^{8}\) Another systematic review of CDSSs in a broad variety of health interventions has shown that improvements can occur in drug dose, clinical diagnosis, preventive care reminders, and quality assurance. \(^{7}\) However, both these reviews awarded higher trial quality scores to trials that randomised by practice, but neither review seemed to take account of the possible exaggeration of results when outcomes were analysed by patient. This systematic review does have limitations.

Firstly, the effects of cluster randomisation may have contributed to the positive findings in two of the trials. \(^{18-21}\) Secondly, the trials were all of similar quality according to Cochrane criteria and generally scored poorly on selection, attrition, and detection bias. Although this was partly because of inadequate or unclear reporting, it is known that inadequate methodological approaches are associated with bias in estimates of treatment effects. \(^{27}\) Thirdly, the outcomes chosen were diverse between the randomised controlled trials, and similar outcomes were frequently not measured in the same way; for example, different blood pressure thresholds were used to denote control of hypertension. \(^{20-21}\) Fourthly, the review only contains a small number of trials, most of which measured multiple outcomes, which may lead to false positive conclusions concerning the effects of intervention because of the play of chance. \(^{20-21}\) Lastly, most of the computer systems and programs were unsophisticated and no true decision support systems were evaluated. For these reasons, and in the light of rapid development of software, studies that evaluate new computer technology are required.

Computers have been applied effectively in the management of other chronic diseases. Improvement in diabetes care has been reported in terms of data collection and interpretation, decision support, and education. \(^{29-30}\) A prototype CDSS has been developed for asthma management, targeted at the primary care setting and based on British Thoracic Society guidelines. \(^{31}\) In anticoagulation management, a CDSS improved patient outcome in terms of level of control, frequency of review, and general acceptability. \(^{12}\) A CDSS has been piloted in lipid management, \(^{33}\) and expert systems have been developed for the treatment
of heart failure and depression. It seems likely that computer use and CDSSs are going to be used in the context of chronic disease management with greater frequency in the future.

An estimated 92% of general practices in Britain are now computerised. In practices in the South West Region that are computerised, 98% of general practitioners use a computer at the time of consultation for accessing patient data and prescribing (C Watkins, personal communication based on an unpublished study). With both the level of computerisation in primary care and the degree of sophistication of software increasing, an opportunity exists for expansion in terms of physician education, patient choices and preferences, measurement of compliance with treatment, and ultimately the combination of probability estimates with patients’ utilities in the form of decision analysis.

With the rule of halves still operating in the UK, hypertension remains an important public health problem. Risk stratification as a means of identifying patients who would benefit most from treatment needs to be pursued. Effective management of hypertension in primary care requires coordinated registration, recall, and review, all of which can be facilitated by computer.

This review shows that computers may have a favourable influence on the uptake and administration of patients in hypertension management. Computer use in this area should be encouraged, particularly with regard to case finding and follow up. The results presented here do not seem to support any benefit in using computers in terms of physician performance and blood pressure control in patients. However, there has been enormous development both in software sophistication and doctors’ use of computers, and further evaluation is warranted. Health authorities should take notice of developments in computer software that will allow effective targeting of resources to patients who are most at risk, and general practices should find ways of increasing their usage of computers in the management of hypertension in their practice population.

We would like to thank Debbie Sharp, Tim Peters, and Christopher Macintosh for comments on the manuscript and Frank Sullivan for help with identifying studies examining the use of computers in general practice.
