THEORY AND METHODS

A landmark for popperian epidemiology: refutation of the randomised Aldactone evaluation study

Elard Koch, Alvaro Otarola, Aida Kirschbaum

In 1999 a great multi-site clinical trial known as the randomised Aldactone evaluation study (RALES) showed that the use of spironolactone importantly reduced complications attributable to chronic heart failure without major negative side effects. Recently, RALES has been questioned by a large scale observational study in the Ontario population. In contrast with predictions, the complications and mortality increased dramatically because of hyperkalaemia, reaching dimensions that from a public health perspective are comparable to an epidemic. This review analyses both researches in the light of Karl Popper’s science theory applying the modus tollens syllogism to the reality proposed by the main empirical enunciations that ensue from its epidemiological designs. RALES is deductively refuted because of the non-fulfillment of auxiliary assumptions that would act as reciprocal potential falsifiers in both studies, taking the logical form of a bi-conditional argument of the type: (a) P-then-Q and (b) Q-if-Xp, Xp being a set of potential falsifiers of Q as part of the explicit falsity content of P. From this popperian model, implications for clinical research are discussed.

A well known parable teaches us that every seed must die to give its fruit. With the thought of Sir Karl R Popper one decade from his death, exactly that is occurring. Popperian critical rationalism starts to give its fruit in the applied sciences and the future of the practice of epidemiology seems to fit in with the popperian approach of what we call, since Carol Buck’s article in 1975, popperian epidemiology. Ever since the decade of the 1980s numerous epidemiologists have approached the subject in a rich and intense philosophical and methodological debate. Although refutationism is one among a number of critical tools for empirical sciences, popperian epidemiology has often been presented as an opposed approach to a paradigm of inductive inference, which represents the presently dominant current in epidemiology. Nevertheless, the recent publication of a populational study carried out in Ontario, Canada, which questions a great multi-site clinical trial such as the randomised Aldactone evaluation study (RALES) revives the discussion about the difficulties in inductively transferring the results of experimental designs to the “real empirical world” of clinical practice and the way in which physicians make use of scientific evidence in the paradigm of evidence based medicine (EBM), nowadays influenced by a positivised critical rationalism. In this article we analyse the results of these studies in the light of Popper’s science theory as far as scientific evidence is concerned and we evaluate the applicability of the falsifiability principle to the main empirical enunciations that emerge from their epidemiological designs.

AN APPROACH TO KARL POPPER’S SCIENCE THEORY

Neopositivism argues in favour of the inductive method by means of the process of justification or verification through repetition (addition of multiple verified cases) formulating the principle of positive verification as a significance criterion that can lead to a degree of certainty or truth, a type of inductive “support”. Popper is opposed to all types of verificationism. The inductive process is not demonstrable in a logical way, as there exists an asymmetry between the part observed and the whole. The problem of induction consists in logically justifying the inductive inferences. Accepting Hume’s arguments, Popper considers that this inductive step is not justified, as there will always exist unobserved cases, no matter how large the number of individual observations may be: thus, we will only reach probable conclusions, and following this road, we come to a situation where there are many theories propounded, all of them probable, but leading to no advance in knowledge. For real progress in knowledge, we must increase empirical content of theories refuting them and correcting their errors, and the rebuttal of theories is conditioned by deductive reasoning that, unlike induction, allows to reach a sure or necessary conclusion.

Opposing the intent of refuting his own theories to the normal intent of verifying them, Popper deduces the falsifiability principle, no longer as a criterion of empirical significance, but as a manner of delimiting what science is and what it is not. A theory is scientific if it can be falsified by means of experience or by means of its internal inconsistency. Falsification is the corroboration that an enunciation is false for not having resisted the falsification test. This procedure does not require a process of induction that is logically impossible, but a simple logical
EBM, seeking maximal safety and efficacy in therapeutic decision making, can diminish the uncertainty and heuristic component of evidence-based medicine. Therefore, its weight will be greater in clinical practice if the evidence proceeding from research as one more verificationist approach. In Popper’s approach a hypothesis must be falsifiable and falsifiability by means of which scientific theories can never be empirically verified, they can be falsifiable by the non-observed cases, and thus the modus tollens turns into the logical rule of the empirical sciences. The induction principle is rejected by Popper because an inductive method, as a logically valid process of contrasting, is inadequate, as theory always precedes observation; it is even necessary for choosing among the innumerable observation objects that are often mentioned as a technological problem for experimental design.

On the basis of scientific deductive methodology, if a series of consequences derives from one theory and at the same time we are able to set forth a series of contradictory statements with those consequences, we have at our disposal a series of potential falsifiers of the theory. For a theory to be falsifiable it has to preclude, as a minimum, one empirical happening. For example, it is what we would usually call inclusion and exclusion criteria in the design of an epidemiological experiment or clinical trial. If the number of possible falsifiers of a theory is greater than that corresponding to another theory in competence, the first theory will have more occasions to be refuted by the experience; therefore, when compared with the second theory, we can say that it is “falsifiable to a larger degree”. It follows that a scientific theory has a greater degree of corroboration when it has resisted more criticisms and has been subject to more severe contrasts and not when it has been more verified. Thus, honesty and scientific objectivity reveal themselves in the formulation of falsifiable theories, which are tested without recurring to stratagems of immunisation against error. Scientific theories are such because of their explanatory, informative, and predictive capacity, not because of their capacity of adapting actual happenings to their conceptual formulation, which can be described as subjective and unjustified defence of a theory, a situation to which methodological inducivism would lead in a verificationist approach. In Popper’s approach a hypothesis will be accepted as provisionally true (corroborated) only when it continues to explain observed data after repeated attempts to falsify it have failed.

Evidence based medicine and randomised clinical trials

EBM has recently been described as the “integration of best research evidence with clinical expertise and patient values”, and a new model of “based on evidence decision-making” has been proposed. Despite the fact that the model considers evidence proceeding from research as one more component of the process, its weight will be greater in clinical decision making with the progress of medical knowledge, thus diminishing the uncertainty and heuristic component of EBM, seeking maximal safety and efficacy in therapeutic interventions. The classification of evidence reliability into the hierarchical levels, according to the scientific rigour of methodological designs, has placed randomised clinical trials (RCTs) and systematic reviews at the highest level, followed by controlled observational studies, and finally by non-controlled studies and expert opinions. Special attention is granted to the evidence provided by large multi-site RCTs over small RCTs. Their main characteristic is that the patients composing the sample are recruited from different parts of the world. The weight of evidence proceeding from these RCTs is often considered decisive for accepting or rejecting new therapeutic interventions, as they provide a greater inductive “support” for generalising their results to the population and can considerably influence the prescription of a drug on clinical practice.

Nevertheless, the hierarchised consideration of evidence can induce a somewhat dogmatic critical rationalism in researchers and clinicians and underrate evidence of smaller RCTs and other epidemiological designs. Despite the fact that RCT is considered to be the epidemiological design of highest scientific rigour on an experimental scale, it has certain limitations. The main presumption of this methodology is that disease variations can be sufficiently quantified as to allow the real probability of differences between active treatment and placebo to have occurred randomly. As long as the number of patients is large enough and a high rate of events, the validity of the study will not be compromised and the results will have clinical value. Nevertheless, with restrictive and standardised conditions increase the internal validity of the conclusions but they negatively affect the external validity, namely the possibility to transfer the results to patients with characteristics different from those of the selected sample. From this perspective, both clinical epidemiology and EBM in practice essentially respond to a model of hypothesis verification and its subsequent generalisation by the inductive method.

The randomised aldactone evaluation study (RALES)

A good example of a great multi-site RCT is the RALES study conducted by Pitt et al involving 195 centres in 16 countries (table 1). The study was designed to evaluate the effectiveness of spironolactone (Searle’s Aldactone), an aldosterone inhibitor in chronic heart failure (CHF). Its main hypotheses were that the use of low doses of this drug combined with a standard therapy of angiotensin converting enzyme (ACE) inhibitors, would importantly reduce the mortality and complications in severe CHF without major negative side effects.

In the RALES study, 1663 patients with severe CHF and no history of renal insufficiency, diabetes, or hyperkalaemia were included. A total of 822 patients were randomly assigned to receive 25 mg of spironolactone daily, and 841 to receive placebo. The study found that spironolactone added to ACE inhibitors and diuretics in patients with CHF attributable to systolic left ventricular dysfunction significantly decreased all cause mortality by 30%, sudden death by 29%, and hospitalisation attributable to advancement of CHF by 35% over two years compared with placebo. The incidence of serious hyperkalaemia was minimal (below 2%) in both groups of patients. The conclusion of its authors was that the block of aldosterone receptors by spironolactone in addition to standard therapy, substantially reduced the risk of both morbidity and death among patients with severe CHF with minimal negative side effects.

This RCT was stopped early (November 1998) and received great attention because of the beneficial effects seen during monitoring. There was a rapid diffusion of its results even before the original article by Pitt et al was available on line in the New England Journal of Medicine.
June 1999. The use of spironolactone blossomed after its publication with greater hopes for the medical community and CHF patients.42

POPULATIONAL REFUTATION IN THE ONTARIO STUDY
This study carried out by Juurlink et al19 was a population based, time series analysis of health care databases in Ontario, Canada, from 1 January 1994 to 31 December 2001. During this period, Ontario had a population of about 12.3 million inhabitants, of which about 1.3 million were 65 years of age or older. The number of patients who were treated with an ACE inhibitor after hospitalisation for CHF rose gradually over time, from 20 820 in early 1994 to 32 283 by late 2001. Before the publication of RALES, 4539 patients hospitalised for CHF were given spironolactone, and after RALES, 12 422 patients. The spironolactone prescription rate remained comparatively constant from early 1994 (34 per 1000 patients) until early 1999 (30 per 1000 patients). After the publication of RALES, the rate of prescriptions increased by a factor of about five, to 149 per 1000 by late 2001 (fig 1).

with the abrupt increment in the prescription rates of spironolactone and, at the same time, with an increment in the morbidity and mortality from hyperkalaemia, recommending the more judicious use of spironolactone and more strict laboratory controls to prevent the complications seen.

One year before the publication of the Ontario study, smaller clinical studies described complications arising from the inappropriate use of spironolactone. From these reports, it was obvious that many physicians were giving spironolactone to patients who did not meet the RALES entry and exclusion criteria. MacMurray and O’Meara point out the incongruence of the inclusion and exclusion criteria of the large RCTs with the “real world” of clinical practice. In this case, the evidence of RALES became manifest in a generalisation of its results beyond the scope of inclusion and exclusion criteria of the study. On the other hand, the concept of inductive “support” leads to a false sensation of safety that would provoke an injudicious use of the drug and subsequent adverse outcomes. Besides, the inclusion and exclusion criteria of the RCTs, which respond to a positive verification model, can partly be considered strategies of immunisation against error, which implies that their generalisation to the population be limited and subsequently hazardous. Finally Goldfarb, as a counterpart, speculates with an ecological fallacy in the Ontario experience due to added uncontrolled morbid conditions.

The Ontario study questions, at a populational level, one of the main conclusions of RALES with respect to the complications seen attributable to hyperkalaemia. According to Popper, all empirical sciences share the same hypothesis deductive method and the modus tollens logical rule, a matter that we will presently analyse in the RALES and Ontario research experiences.

LOGICAL ARGUMENTATION

According to Lakatos and other falsificationist philosophers, no hypothesis is outright falsified, but only a hypothesis along with an unspecified number of auxiliary assumptions. Keeping this in mind, RALES and the Ontario study follow a time dependent sequence of events forming a complete logical analysis unit and modus tollens in its simplest form (P-then-Q; no-Q; then no-P) it can be expressed as: “spironolactone is associated to minimal complications by hyperkalaemia” represented by the symbol P, and its logical consequence as: “spironolactone in Ontario will be associated to minimal complications by hyperkalaemia” represented by the symbol Q. In contrast with what was anticipated, use of spironolactone was associated to an increase in complications by hyperkalaemia. In this case the observational predicate “increase in complications” is represented by the symbol no-Q and therefore the assertion of P “minimal complications” is false (no-P). Nevertheless, the corroborated of RALES is more complex and assumes the form of a bi-conditional proposition of the type (i) P-then-Q and (ii) Q-if-XP, the symbol XP representing the exclusion and inclusion criteria of the study. Let XP be the series of observational predicates X1, X2, X3,...Xn as explicit falsity-content of P and therefore, a series of potential falsifiers of Q. Expressed as a canonical logical argumentation: (i) If P-then-Q, and (ii) Q-if-XP, XP being (iii) the series X1, X2, X3,...Xn and (iv) no-XP then (v) no-Q, (vi) no-Q then (vii) no-P. Deductively no-XP can be any criterion of inclusion or exclusion or conditional criterion of RALES that was not fulfilled in the Ontario population (table 2), for example, let X3 be “patients with a fraction of ejection of the left ventricle <35%”, X4 “diabetic patient”, X14 “close laboratory monitoring”, etc. In this sense, it would suffice for one of these auxiliary assumptions contained in XP to be false so that Q were not fulfilled and P would result refuted. From the beginning, RALES included numerous

Figure 2. Rate of hospital admission for hyperkalaemia among patients for CHF in Ontario, Canada, 1994 to 2001. Each bar shows the observed spironolactone prescription rate per 1000 patients during one four-month interval. The horizontal line beginning in the second interval of 1999 shows projected admission rates for hyperkalaemia derived from interventional ARIMA models, with vertical lines representing the 95% confidence intervals. Thus increases the prescriptions for spironolactone in Ontario''. spironolactone'' and its logical consequence P
the proposition ''…RALES increases the prescriptions for
content of
on a speculative scale, but it remains included in the falsity
spironolactone''. A possible ecological fallacy can be set forth
of the proposition
predicates (because both studies predict their contradictory observational
was seen (ing evidence.19 It is also logically consistent at a populational
level of analysis and reciprocally we could speculate an
individualistic fallacy52 in the RALES design. We can set forth
the following set of enunciations:

- H = "… RALES increases the prescriptions of spirono-
lactone"
- O = "…RALES increases the prescriptions of spirono-
lactone in Ontario"
- P = "…spironolactone increases hyperkalaemia complica-
tions"

Q = "…spironolactone increases hyperkalaemia in
Ontario"

The corroboration that took place in Ontario is: (i) H-then-
O; (ii) O-then-P and (iii) P-then-Q, so that the conclusion
predicted in the empirical scale is made by logical synthesis
(iv) H-then-Q, a logically valid problem for Ontario’s public
health which remains unfalsified.

**ECOLOGICAL FALLACY**

Although the Ontario experience does not isolate one or
several of the auxiliary assumptions contained in Xp that are
guilty of the increase in complications, the basic population
may contain other potential falsifiers not included in the
RALES criteria, giving place to a possible ecological fallacy.53 54 Conjectures set forth by different authors53 54 55 that explain these contradictory results are that spironola-
tone was systematically used beyond the RALES inclusion and exclusion criteria, this means that the conditional
argument Xp of Q results to be false. The ecological design of Ontario admits the submittal of a fundamental hypothesis
to falsification so as to corroborate this hypothesis. Let H be
the proposition "…RALES increases the prescriptions for
spironolactone” and its logical consequence P "…RALES
increases the prescriptions for spironolactone in Ontario”. Thus H-then-P results corroborated because this phenomenon
was observed in Ontario after the publication of RALES.
Consequently an increase in hyperkalaemia complications
was seen (no-Q) that contradicts the RALES prediction (Q),
because both studies predict their contradictory observational
predicates (Q and no-Q) starting from the logical consequence of the proposition P, whose subject is “prescription of
spironolactone”. A possible ecological fallacy can be set forth
on a speculative scale, but it remains included in the falsity
content of Xp, that is, everything that is not RALES. Juurlink
et al conclude that the relation established is temporarily
compelling, biologically plausible, and consistent with exist-
ing evidence.56 It is also logically consistent at a populational
level of analysis and reciprocally we could speculate an
individualistic fallacy53 in the RALES design. We can set forth
the following set of enunciations:

- Q = "…spironolactone increases hyperkalaemia in
Ontario”

**DISCUSSION**

Two criticisms, important for epidemiological science have
been proposed to Popper’s original falsificationist theory.
Firstly, no hypothesis is outright falsified, but only a

What this paper adds

- This paper presents two studies with contradictory results that are in a synchronic relation, forming a complete logical analysis unit: one hypothesis corroborated experimentally in an RCT confronted with a populational reality of an observational study in which its predictions are questioned.
- A basic logical structure is presented for a refutationist analysis of RCTs using bi-conditional modus tollens arguments in the form of (i) P-then-Q and (ii) Q-if-XP, XP being a set of potential falsifiers of Q (predictions in the population) as part of the explicit falsity content of P (corroborated hypothesis).
- It is shown, following a deductive, canonical, logical argumentation, that the falsifiability of an RCT is determined by explicit auxiliary assumptions in the empirical content of XP (criteria of inclusion, exclusion, and conditional criteria) restricting its external validity.
- This logical model constitutes the basis for the development of quantitative methods allowing a probabilistic approach to the falsifiability degree (probability of Q-if-XP) and generalisability (probability of XP) of experimentally corroborated hypotheses in specific populations.
- Both RALES and the Ontario study have allowed to hypothesise the popperian model presented in this article. In practice, not to follow a deductive reasoning, transferring the results of RALES to Ontario, is a logical error with negative public health consequences.
- Popperian epidemiology is an important critical tool that should be incorporated by the EBM authors in the analysis and discussion of the external validity of multinational RCT papers that will permit an effective and safe transfer of the evidence to clinical practice.

hypothesis along with an unspecified number of auxiliary assumptions. Secondly, corroborations statements would have no predictive content. Although they motivate and justify our preference for some theory over another, generalisations involved in drawing predictive conclusions should be rationally supported, so that the induction cannot be totally disproved in empirical sciences. Nevertheless, this pragmatic justification of induction has been controversial in epidemiology, as it would also justify to be illogical, quick, imprecise, and uncritical in analysing data and writing papers. In contrast, epidemiological scientists should be meticulous, precise, critical observers who are rigorous in their use of logic. Epidemiological analysis is not only a problem of empirical observation and pragmatism but a process of logical and theoretical construction. Thus, the refutationist approach is an important critical tool for epidemiology and there are many examples in medical research that support the utility of Popper’s philosophical principles.

The falsifiability of scientific hypotheses justifies the need for experimentation, a demarcative criterion widely recognised by different medical scientists. Recently, Hyams illustrates how non-falsifiable hypotheses are insufficient to advance in medical knowledge, even when there is an abundance of inductively supported empirical data. If popperian epidemiology is incorporated to clinical research, hypotheses will be ranked as scientific when they can be tested and falsified. In our study, both RCT and ecological designs are in good accord with the principle of falsifiability of their scientific enunciations and their logical rule, the modus tollens, although in practice the evidence appears as being treated in an exclusive inductive model. Researchers in multinational RCTs assume that the clinical effects of the therapies under study are homogeneous from one country to another, centring the discussion of their reports more on the internal validity than on the external validity of the results. Thus, a critical rationalism sustained exclusively on the principle of positive hypotheses verification and of inductive “support” provided by large multi-site RCTs can lead physicians to a false sensation of safety and iatrogenic use of evidence with unfavourable consequences for public health as has been the case with RALES.

Canonical logical analyses applied to epidemiological studies are not frequent in the literature and they appear with popperian epidemiology. In the present falsificationist science metatheory, a theory’s content is the totality of its logical consequences; its true consequences constitute its truth content and its false consequences, if any, its falsity content. This means that, when transferring the experimental results to the “real world”, all the empirical content of the tested hypotheses is transferred. From this perspective, the ecological design of Ontario, based on a population, represents a part of the “real world”, and RALES, a corroborated hypothesis that has been moved to this “real world”, so that both studies are in synchronous relation, forming a complete logical analysis unit. In Ontario, RALES would be refuted for the non-fulfilment of its auxiliary assumptions represented by its inclusion and exclusion criteria, which act as reciprocal potential falsifiers in both studies, taking the logical form of a bi-conditional argument of the type (i) P-then-Q and (ii) Q-if-XP, XP being a set of potential falsifiers of Q (predictions in the population) as part of the explicit falsity-content of P (corroborated hypothesis). In this model ecological fallacy and confounders remain included in the falsity content of XP and falsifiability of RCTs is logically determined by the empirical content of the argument Q-if-XP. Thus, an estimation of the generalisability degree is possible knowing the probability of XP in specific populations. In the same way, the probability of Q-if-XP would be an estimator of the falsifiability degree, so that Bayesian models starting from bi-conditional modus tollens arguments can be adapted to evaluate falsifiability of RCTs from observational designs, and identify other potential falsifiers, thus allowing to raise new testable hypotheses.

To summarise, no epidemiological study logically contributes more than what is contained in its design. In their turn, auxiliary assumptions on RCTs act as potential falsifiers of the empirical reality they propose, that is, RCTs contain, in their experimental designs, the limits of their applications. In practice, not to follow a deductive reasoning by moving RALES results to Ontario, is to say (i) P-then-Q and (ii) Q-if-XP, is a logical error with unfavourable consequences for public health. It being impossible to logically justify induction, pragmatic justification is the only alternative, nevertheless, pragmatism can also justify mistakes and epidemiological imprecisions. Lastly, popperian epidemiology would be a beneficial critical tool for EBM facing fundamental issues in multinational RCT papers, especially, the largely unresolved problem of external validity.

ACKNOWLEDGEMENTS

We express our acknowledgments to Dr Carol Buck, author of the noteworthy article “Popper’s philosophy for epidemiologists”. She died on 29 April 2004, at the age of 79. We are indebted to reviewers for their extensive criticisms and valuable suggestions for this manuscript.
