Risk of autism spectrum disorders in children born after assisted conception: a population-based follow-up study

D Hvidtjørn, J Grove, D Schendel, L A Schieve, C Sværke, E Ernst, P Thorsen

ABSTRACT

Objectives To assess the risk of autism spectrum disorders (ASD) in children born after assisted conception compared with children born after natural conception.

Design Population-based follow-up study.

Participants 588,967 children born in Denmark from January 1995 to December 2003. Assisted conception was defined as in vitro fertilisation (IVF) with or without intracytoplasmic sperm injection (ICSI) and ovulation induction (OI) with or without subsequent insemination. Children exposed to IVF or OI were identified in the IVF Register and in the Danish Drug Prescription Register.

Main outcome measures A diagnosis of ASD in the Danish Psychiatric Central Register.

Results 33,139 (5.6%) of all children born in Denmark in 1995—2003 resulted from assisted conception, 225 of whom (0.68%) had a diagnosis of ASD. Of the 555,828 children born in this period after natural conception, 3,394 (0.61%) had a diagnosis of ASD. The follow-up time was 4—13 years (median 9 years). In crude analyses, children born after assisted conception had an increased risk of a diagnosis of ASD: crude hazard rate ratio (HRR) 1.25 (95% CI 1.09 to 1.43). In analyses adjusting for maternal age, educational level, parity, smoking, birth weight and multiplicity, the risk disappeared: adjusted HRR 1.13 (95% CI 0.97 to 1.31). However, subgroup analyses that suggest possible associations in women who received follicle stimulating hormone indicate the need for further study.

Discussion This population-based follow-up study found no risk of ASD in children born after assisted conception.

INTRODUCTION

The aetiology behind infantile autism and autism spectrum disorders (ASD) is multifactorial and largely unknown. Associations between ASD and assisted conception might be anticipated because of at least three shared risk factors: high parental age, high maternal educational level and hormonal disturbances. Furthermore, a higher risk of ASD in children born after assisted conception might be expected since assisted conception leads to a high rate of preterm delivery (PTD) and low birth weight (BW). Associations between PTD or BW and ASD have been reported. The use of assisted conception has increased over the last two decades.

We identified eight studies assessing the risk of infantile autism or ASD in children born after assisted conception. They present inconsistent results and disclose methodological problems such as lack of statistical power or only evaluating a combined group of psychiatric disorders, rather than ASD specifically. Furthermore, six studies only assessed one type of assisted conception, in vitro fertilisation (IVF). In all, only one study found a significantly higher occurrence of ASD in children born after assisted conception compared with children born after natural conception; however, four other studies reported a non-statistically significantly increased risk. One case—control study reported a protective effect of assisted conception on infantile autism after adjusting for several factors including gestational age. None of the studies distinguished between different underlying causes of infertility or between different types of medications used in the treatment. Consequently, the relationship between ASD and assisted conception is still not well understood. To overcome methodological problems in former studies, we assessed the risk of infantile autism and ASD in a large population-based cohort of children born after assisted conception. Assisted conception was defined as IVF with or without intracytoplasmic sperm injection (ICSI) and ovulation induction (OI) with or without subsequent in semination. We also evaluated underlying causes of infertility and specific medications used in the treatments.

METHODS

Study population

This cohort study was based on data from Danish National Registers and linkage between the registers was achieved by use of the unique registration number given to all citizens in Denmark. Our study comprised all children born alive in Denmark from 1 January 1995 to 31 December 2003, identified through the Danish Medical Birth Register (MBR) which contains information on all births in Denmark.

Exposure

Children exposed to IVF were identified through the IVF Register which holds data from all private and public fertility clinics including underlying causes of infertility (tubal, male, ovulation or mixed and unspecified factors). Children exposed to OI were identified through the Danish Drug Prescription Register (DDPR) which holds information on all prescription drugs sold at pharmacies in Denmark. The medications used during OI are prescription drugs bought at the pharmacy, enabling identification of the women who went through OI in the DDPR. Drugs used in assisted conception...
were identified by the authors by cross-checking with the official Danish Pharmaceutical Classified Catalogue, www.medicin.dk, the US website www.drugs.com, books of instruction of Danish fertility clinics from the time period in question and by means of clinical experience. To identify women who had hormonal treatment in relation to the index pregnancy, we set up a time window for the date of dispatch of 12 weeks before and 4 weeks after the last menstrual period (LMP). As the drugs used in OI are also used in IVF, we excluded women from the OI group who were included in the IVF Register with the same LMP date.

**Outcome**

Children with a diagnosis of ASD (F84.0, F84.1, F84.5, F84.8 and F84.9) or, specifically, infantile autism (F84.0) up to 8 May 2008 were identified via the Danish Psychiatric Central Register (DPCR). The DPCR contains information on all Danish psychiatric inpatient and outpatient admissions since 1995,33 and in Denmark all autism diagnoses are made at public child mental health services, reporting all inpatient and outpatient discharge diagnoses to the DPCR.

**Covariates**

Further covariate information was obtained from MBR and Statistics Denmark: BW, gestational age, multiplicity, sex, maternal age, educational level, smoking and parity. Maternal age was divided into 5-year age groups: 20–24, 25–29 (referred category), 30–34, 35–39, 40+; BW was grouped into 500–1499 g, 1500–2499 g and normal BW ≥2500 g (referred category); education level was categorised as low (9–10 years of education), intermediate (11–16 years of education) (referred category) and high (≥17 years of education); parity was dichotomised into primiparous and multiparous (referred category); multiplicity was divided into singletons (referred category) and multiples; and maternal smoking during pregnancy was grouped into non-smoker (referred category) and smoking plus ‘stopped smoking during pregnancy’ combined. As there were no mothers aged <20 years in the IVF Register, 10137 children (1.7%) born to mothers aged <20 years were excluded.

**Multivariate analyses**

Cox regression was used to measure the risk of an ASD diagnosis in children born after assisted conception combined and in IVF and OI separately. We conducted multivariate analyses including maternal age, parity, smoking, educational level, BW and multiplicity. Owing to the skewed sex distribution in ASD, analyses were conducted for all children and stratified by sex.

**Sub-analyses**

In further analyses we explored if the risk of ASD was associated with a single underlying cause of infertility (tubal, male, ovulation or mixed and unspecified factors), but this information was only available in the IVF Register and only for 9855 (66%) of the IVF children as many of the IVF children had unspecified or more than one cause. Finally, to examine if different hormones used in assisted conception (downregulating hormones, clomiphene, follicle stimulating hormone (FSH) and human chorionic gonadotropin (hCG)) were associated with ASD, we made exploratory analyses with specific hormone exposure. Information about the use of specific hormones was available from the DDPR for all OI children but only for 51% of the IVF children. This was due to different dispensing procedures at IVF clinics; some clinics dispense the medication directly to the women while other IVF clinics provide prescriptions for the pharmacy. Only the latter group of women is included in the DDPR.

**Statistical analyses**

The risk of a diagnosis of ASD or infantile autism was measured by the incidence rate, using the child as the unit of analysis. The incidence rate was defined as the number of children diagnosed with ASD in a given time frame (1 January 1995 to 8 May 2008) divided by the total number of person-years the children in the cohort were at risk for the diagnosis during that time. We used Cox regression and the incidence rate ratio was estimated by the hazard rate ratio (HRR) with 95% CIs. It was verified that the proportional hazards assumption was met. To account for correlations between siblings in the cohort, additional analyses were done using robust standard errors. To reduce bias that might arise if exposed children at high risk for ASD were more likely to die as infants than unexposed children, we conducted additional analyses excluding children aged <1 year (ie, limiting the analysis to infant survivors).

**RESULTS**

From 1 January 1995 to 31 December 2003, 588967 children were born alive in Denmark to 399598 mothers aged ≥20 years. In this period, 35139 (5.6%) children resulted from assisted conception, 14991 (2.6%) from IVF and 18148 (3.0%) from OI. Compared with mothers who conceived naturally, those with assisted conception were statistically significantly older (p = 0.001), more often primiparous (p < 0.001), non-smokers (p = 0.001), had higher educational level (p = 0.002) and delivered more multiples (p = 0.001), children with low BW (p < 0.001) and FTD (p = 0.001) (table 1). Furthermore, the difference in most of these characteristics from mothers who conceived naturally was greater for mothers having IVF than for those having OI (table 1).

Up to 8 May 2008, 3619 (0.61%) children from the cohort were diagnosed with ASD; a diagnosis of infantile autism was given to 1385 children (0.24%). For all diagnoses, the follow-up time was 4–13 years (median 9 years). Within the time period 1995–2003, 3479 mothers had one child with a diagnosis of ASD, 64 mothers had two children with an ASD diagnosis and 4 mothers had three children with a diagnosis of ASD. Mothers of children with ASD were significantly different from mothers of other children in selected characteristics: they were older (p < 0.001), more often primiparous (p < 0.001), smokers (p < 0.001), they had a higher or lower educational level (p < 0.001), more preterm deliveries (p < 0.001) and children with low BW (p < 0.001) (table 2).

In children born after assisted conception, the risk of having a diagnosis of ASD or infantile autism was increased (crude HRR 1.25 (95% CI 1.09 to 1.43) and 1.25 (95% CI 1.01 to 1.54), respectively). The crude HRR for the risk of a diagnosis of ASD was 1.18 (95% CI 0.95 to 1.44) for children born after IVF and 1.31 (95% CI 1.10 to 1.56) for those born after OI. In analyses adjusted for maternal age, educational level, smoking, parity, BW and multiplicity, we found a HRR of 1.13 (95% CI 0.97 to 1.31) in the combined assisted conception group and higher risk estimates in OI than in IVF (table 3). In the adjusted analyses, only girls born after OI had a statistically significant increased risk of ASD.

Similar results were seen for infantile autism but with wider CIs (data not shown). The risk of ASD for boys and girls did not differ significantly. Restricting the analyses to infants who survived their first year showed similar results to the full cohort (data not shown). Dropping variables from the adjusted analyses
one at a time showed that the increased risk in the crude analyses seemed to be explained by maternal age and parity but not by smoking, multiplicity, BW and educational level. The HRR in an adjusted analyses not including maternal age was 1.24 (95% CI 1.13 to 1.35). The increased risk for ASD in children born after assisted conception (adjusted HRR = 1.28 (95% CI 1.10 to 1.49)). The risk was higher for girls than for boys for all hormones and statistically significant for FSH, hCG and clomiphene. We were able to assess FSH use in all OI treatments but only in 51% of the IVF treatments as we could not confirm the specific medications used through the DDPR for the remaining IVF treatments. Women who underwent IVF and had detailed medication data from DDPR were different from those without DDPR data in that they were older, more often multiparous, non-smokers, more highly educated and more likely to have been treated at a private rather than a public clinic. They were also more likely to have ovulation factor infertility; however, even with this increase, it is important to note that, while the majority of women who underwent IVF and had detailed medication data from DDPR used FSH (85%), in only a small minority (9%) was ovulation factor infertility documented. We were unable to assess both factors simultaneously because of limited sample size (only 58 cases had data on both the single underlying cause of infertility and specific hormone treatment).

DISCUSSION
Main results
In this large population-based cohort study we found no risk of ASD in children born after assisted conception (adjusted HRR = 1.13 (95% CI 0.97 to 1.31)). The increased risk for ASD observed in unadjusted analyses seemed to be related to high maternal age and parity but did not appear to be related to educational level, low BW, smoking or multiplicity. This is the
largest population-based study to date, with 53,199 children exposed to assisted conception, and hence the first study also permitting assessment of different types of assisted conception separately. In the present study the prevalence of ASD was 6 per 1000 children, similar to reports from other studies where sexes separately. In the present study the prevalence of ASD was 6 in girls (third and over). In our analyses the risk of ASD from assisted conception did not remain statistically significant when we adjusted for parity, suggesting that the increased risk of ASD in the crude analyses is also partly explained by a large proportion of primiparous mothers having assisted conception.

In assisted conception more children are born with low BW and, in general, the risk of ASD increases with decreasing BW in most studies, although not in one smaller study by Glasson et al using mean BW. In our study, low BW did not seem to explain the increased risk of ASD in assisted conception. This is in contrast to studies of cerebral palsy where the increased risk of cerebral palsy in children born after IVF is partly explained by multiplicity and PTD, factors leading to a high proportion of low BW children.

Other studies
Our results contradict previous studies which found a higher occurrence of ASD in children born after assisted conception, using mean BW. In our study, low BW did not seem to explain the increased risk of ASD in assisted conception. This is in contrast to studies of cerebral palsy where the increased risk of cerebral palsy in children born after IVF is partly explained by multiplicity and PTD, factors leading to a high proportion of low BW children.

Type of assisted conception
There was a tendency for higher risk estimates in the OI group than in the IVF group, but the differences in risk between the two types of treatment were not statistically significant. However, this trend was consistent in both boys and girls with ASD and might be explained by competing risk factors in the IVF group, as this group is at higher risk of ASD a priori owing to higher maternal age, more multiple pregnancies and more primiparous mothers (table 1). However, the risk of ASD was not statistically significant in the adjusted analyses in either type of assisted conception.

Data shown as numbers (percentages). Children without autism spectrum disorders (ASD) compared with children with ASD.

Sex, maternal age, parity and birth weight
The risk from assisted conception tended to be higher in girls than in boys in all groups. Other studies suggest that the aetiological profile behind ASD in girls and boys may be different. Furthermore, since the a priori risk in boys is so much higher than the risk in girls, it is possible that ASD in boys represents either a more heterogeneous mix of autism aetiological subtypes or a mix of potential aetiologies which could moderate an association of assisted conception with ASD.

The risk of autism or ASD is associated with advanced maternal age in some studies with adjusted analyses but not in all. A recent meta-analysis found an increased risk in both first-born and subsequent children (third and over). In our analyses the risk of ASD from assisted conception did not remain statistically significant when we adjusted for parity, suggesting that the increased risk of ASD in the crude analyses is also partly explained by a large proportion of primiparous mothers having assisted conception.

In the assisted conception more children are born with low BW and, in general, the risk of ASD increases with decreasing BW in most studies, although not in one smaller study by Glasson et al using mean BW. In our study, low BW did not seem to explain the increased risk of ASD in assisted conception. This is in contrast to studies of cerebral palsy where the increased risk of cerebral palsy in children born after IVF is partly explained by multiplicity and PTD, factors leading to a high proportion of low BW children.

Other studies
Our results contradict previous studies which found a higher occurrence of ASD in children born after assisted conception. One case–control study showed a protective association between a general notation of assisted conception on the birth record and infantile autism. The possibility of biased exposure ascertainment cannot be ruled out in the latter case–control study.

Hormonal exposure

In adjusted analyses an increased risk of ASD from FSH exposure was seen (HRR 1.44 (95% CI 1.16 to 1.80)). The risk was statistically significant in both boys and girls but, when specific treatments were considered, the risk was only statistically significant in IVF. Hormonal disorders could link assisted conception with ASD as some underlying causes of infertility are hormone-related and hormonal medications are used as part of infertility treatments. Furthermore, various theories for associations between abnormal levels of sex hormones and ASD have been presented, based on reports of increased levels of fetal testosterone in children with ASD, women with ASD having significantly more polycystic ovary syndrome, delayed puberty and irregular menstrual cycles in adulthood than controls, and children with ASD having significantly lower levels of serum FSH and significantly higher levels of serum total testosterone relative to normal reference ranges. Our findings concerning the risk of ASD following specific hormone exposure in assisted conception should be interpreted with caution. In treatment regimes in assisted conception, hormones are used in various combinations and hormone exposure groups therefore overlap. We did not have data to assess specific medication dosages or protocols. However, we were able to assess FSH use in all OI treatments but only in 51% of the IVF treatments as we could not confirm the specific medications used through the DDPR for the remaining IVF treatments. We therefore could not assess medication use in the context of the underlying fertility condition being treated. It is therefore unclear whether it is factors linked to use of FSH (underlying cause of infertility or other conditions), a teratogenic effect from FSH medication per se, the combined effect of exogenous FSH on the endogenous hormonal profile or some perhaps yet unmeasured factor which underlies the association between FSH medications and ASD. The risk of ASD in different hormone regimes would best be assessed in a randomised controlled trial, but this possibility is ruled out by the infrequency of ASD. Observational studies such as this are therefore the only alternative, but our findings indicate the need for further more specific investigations of possible associations between exposure to exogenous FSH and ASD.

Strengths and limitations of the study

Our sources of data were Danish National Health Registers. These registers are maintained for administrative or monitoring purposes and will therefore not always include specific details desirable for research. For exposure to IVF we used the IVF Register and, according to the Danish legislation, it is mandatory for all public and private fertility clinics in Denmark to report all initiated IVF and ICSI treatments, successful or not, to the IVF Register and the register is therefore considered almost complete. For exposure to OI we used the DDPR with data on all dispatched prescriptions for hormones used in OI. The main purpose of the DDPR is entirely administrative, that is to ensure that the prescription is not used twice, and therefore it is expected that all dispatches are reported to the DDPR. However, it was not possible to establish the date on which the woman actually administered the medicine. Hormones used in OI can be prescribed for the next three cycles and, consequently, we had to select a time window of prescriptions within 3 months before LMP to define the use of OI in the index pregnancy. Therefore, the hormones could have been administered 1 or 2 months earlier than the index pregnancy. In addition, we cannot be sure that the woman ever administered the medicine she purchased and therefore the findings regarding OI have to be interpreted with caution. However, we have no reason to believe such exposure misclassification would be related to ASD so, to the extent that we erroneously included some children born by natural conception in the OI category, our results might actually be attenuated. The quality of autism diagnoses found in the DPCR has been validated by experts, after evaluating almost 500 medical records of children registered with infantile autism in the DPCR, 94% of the children met the criteria for a correct diagnosis.

As a number of children were followed for <6 years, some children with ASD may not have been diagnosed before the end of follow-up. Also, since the number and proportion of assisted conceptions increased over the study period, a disproportionate number of children born after assisted conception had a shorter follow-up time than naturally conceived children. To deal with these aspects of the data we used Cox regression models in the statistical analysis which account for differences in follow-up time.

CONCLUSION

In conclusion, we found no overall increased risk of ASD in children born after assisted conception. However, in sub-analyses we did find an increased risk in a subgroup of women who had OI treatment and were exposed to FSH. Additional studies with more detailed information on underlying causes of infertility and use of specific hormonal medications may help to pinpoint the underlying mechanism of this increased risk.

Reference: natural conception, adjusted for maternal age, education, parity, smoking, body weight and multiplicity.

ASD, autism spectrum disorders; FSH, follicle stimulating hormone; HCG, human chorionic gonadotropin; IVF, in vitro fertilisation; OI, ovulation induction.

What is already known on this subject

- The few studies that have assessed the association between autism spectrum disorders (ASD) and assisted conception present inconsistent results and disclose methodological limitations such as lack of statistical power.
- Associations between ASD and assisted conception might be anticipated owing to at least three shared risk factors: high parental age, high maternal educational level and hormonal disturbances.
- A higher risk of ASD in children born after assisted conception might also be expected since assisted conception leads to a high rate of preterm delivery and low birth weight, and associations between preterm delivery or low birth weight and ASD have been reported.

What this study adds

- This population-based follow-up study found no risk of ASD in children born after assisted conception.
- However, we did find an increased risk in a subgroup of women who had IVF treatment and were exposed to follicle stimulating hormone.

Funding

The study was funded as a co-financed PhD project by The Danish Agency for Science, Technology and Innovation, University of Aarhus and The Elsass Foundation. Further funding was supplied by Sofiefonden, The Health Insurance for Science, Technology and Innovation, University of Aarhus and The Elsass Foundation.

Competing interests

None.

Ethics approval

Approval for this study was obtained from the Danish Data Protection Agency.

Contributors

DH, PT and JG were responsible for conception and design. DH, JG and CS conducted the statistical analyses and the interpretation of data. DH wrote the first draft of the manuscript. All authors provided critical input at all stages and critically reviewed and contributed to the final draft. PT and DH are guarantors of the study. All authors had full access to the data.

Provenance and peer review

Not commissioned; externally peer reviewed.
