ABSTRACT

Background Neighbourhood quality has been connected with an array of health issues, but neighbourhood research has been limited by the lack of methods to characterise large geographical areas. This study uses innovative computer vision methods and a new big data source of street view images to automatically characterise neighbourhood built environments.

Methods A total of 430,000 images were obtained using Google’s Street View Image API for Salt Lake City, Chicago and Charleston. Convolutional neural networks were used to create indicators of street greenness, crosswalks and building type. We implemented log Poisson regression models to estimate associations between built environment features and individual prevalence of obesity and diabetes in Salt Lake City, controlling for individual-level and zip code-level predisposing characteristics.

Results Computer vision models had an accuracy of 86%–93% compared with manual annotations. Charleston had the highest percentage of green streets (79%), while Chicago had the highest percentage of crosswalks (23%) and commercial buildings/apartments (59%). Built environment characteristics were categorised into tertiles, with the highest tertile serving as the referent group. Individuals living in zip codes with the most green streets, crosswalks and building type exhibited lower obesity and diabetes prevalence at the individual level.

Conclusion Neighbourhood conditions may influence chronic disease outcomes. Google Street View images represent an underused data resource for the construction of built environment features.

INTRODUCTION

Neighbourhood characteristics influence physical and mental health, health behaviours, and the ability of individuals and families to access necessary resources for maintaining good health. Neighbourhood quality has been connected with mortality risk, life expectancy, mental health, self-rated health, obesity and diabetes—even after accounting for compositional characteristics of residents. Adverse conditions concentrate in poor and minority neighbourhoods, thereby increasing health disparities. In a recent study of Seattle, San Diego and Baltimore, neighbourhoods with lower socioeconomic status and higher proportions of racial/ethnic groups had poorer aesthetics (eg, unmaintained buildings, graffiti, broken windows and litter). Conversely, neighbourhoods with higher socioeconomic status and lower proportions of minorities had better pedestrian amenities in terms of sidewalks, crosswalks and intersection control features.

Currently, detailed neighbourhood data come from neighbourhood surveys, administrative data such as the census and systematic inventories of neighbourhood features. Subjective assessments of neighbourhoods from community residents help identify factors that residents believe are most important to their health and increase understanding of how individuals differentially use and interact with their environment. However, self-reported neighbourhood data can be encumbered by several biases, including same-source bias (when two variables appear correlated because information was gathered using self-reported data on both variables) and social desirability bias (inaccuracies caused by a desire by the respondent to give answers that they think will be viewed favourably). Neighbourhood audits of built environmental features have heretofore been conducted using costly, time-consuming onsite visits or manual annotation of samples of street segment images. The development of data algorithms that can automatically process street segments to create indicators of the physical environment would dramatically lower costs and offer new resources for neighbourhood research. In this study, we leverage publicly available and pervasive Google Street View images to derive indicators of neighbourhood built environments. Google Street View had captured 20 petabytes of data, equivalent to 5 million miles of road around the world. We limit this study to the USA. We obtained permission from Google Street View to use their image data for this research project.

Study aims

The purpose of this study is to construct built environment indicators using computer vision techniques and publicly available Google Street View images, and to examine relationships between neighbourhood built environments, demographic
METHODS
Street view image collection
We built algorithms to process image data for Chicago, Charleston and Salt Lake City between December 2016 and February 2017. Using Google’s Street View Image API, we obtained image data on all road intersections and a random sample of street segments approximately 50 m apart. At each search location, we obtained street view images to the west, east, north and south to capture features of the environment. Image resolution was 640×640 pixels. In total, 227000 images were obtained for Chicago, 150000 for Salt Lake City and 53000 for Charleston.

Image data processing
Convolutional neural networks21 achieve state-of-the-art accuracy for several computer vision tasks including object recognition, object detection and scene labelling.22–24 To create a training dataset for our computer vision models, we manually annotated 14000 images. Each image had three binary labels for the following neighbourhood characteristics: (1) presence of a crosswalk (yes/no), (2) building type (single-family detached house vs other) and (3) street greenness/landscaping (street trees and street landscaping comprised at least 30% of the image (yes/no). A cut-point of approximately 30% was used to assist with inter-rater reliability in manual annotations of street greenness. Moreover, we found that most images had some street landscaping and aimed to create a neighbourhood indicator to distinguish between ample and sparse street landscaping. Images were manually labelled by four of the authors. Inter-rater agreement was above 85% for all neighbourhood indicators (86%–96% for crosswalks; 85%–90% for building type; 85%–95% for green30). We randomly divided each labelled image dataset into a training set (80%), used to calibrate the model, and a test set (20%), used to evaluate the trained model’s accuracy. We used a deep convolutional network (Visual Geometry Group (2018), used to evaluate the trained model’s accuracy. We used a deep convolutional network (Visual Geometry Group, 2018) and ICD-10 codes (E11.40’, ‘E10.9’, ‘E10.29’, ‘E11.51’, ‘E11.29’, ‘E11.36’, ‘E10.36’, ‘E10.39’, ‘E10.51’, ‘E10.40’, ‘E10.65’, ‘E11.21’, ‘E11.319’, ‘E10.319’, ‘E11.65’, ‘E11.311’, ‘E11.39’, ‘E10.21’, ‘E10.311’, ‘E11.9’). Sources of the clinic data included the University of Utah Health Sciences Center Enterprise Data Warehouse and Utah’s Department of Health inpatient and ambulatory surgery data.

Covariates
We included individual sociodemographic characteristics along with health/disease predispositions to adjust for potential confounding of the relationship between neighbourhood environments and adult chronic disease. Covariates included age (years), sex (male/female), marital status (married vs divorced/single), non-White race, ethnicity and education (less than high school, high school, some college, college or greater). We used education information appearing on the Utah birth certificates of their children (if any).

Zip code characteristics
We used zip code boundaries as a working definition of neighbourhoods. To examine how Google-derived neighbourhood variables relate to more traditional neighbourhood variables, we merged our image dataset with 5-year estimates (2011–2015) from the American Community Survey which comprised the following zip code-level characteristics: population density, percentage of the population 65 years and older, percentage of Hispanics, percentage of blacks, median household income and percentage of householders living in current residence for 5 or
more years. We investigated property values as a covariate but excluded it from the model because it was highly correlated (r = 0.93) with median household income.

**Analytic approach**

Choropleth maps were created using ArcGIS Desktop software (ESRI) and the 2016 U.S. Census TIGER/Line Shapefiles. We used tertile breaks in displaying spatial data patterns. A one-to-many spatial join was performed with the image locations and zip codes in order to aggregate the image results into geographical areas. We implemented adjusted linear regression models to examine associations between area-level built environment characteristics and other area-level characteristics (ie, demographics and economic characteristics). To examine the relationship between built environment characteristics and individual-level health outcomes, we merged administrative and medical records from the Utah Population Database to zip code summaries of built environment characteristics. We implemented log Poisson regression models to estimate prevalence ratios (95% CIs) representing associations between tertiles of built environment characteristics and individual chronic disease prevalence. SEs were adjusted for clustering of values at the zip code level. Statistical analyses were implemented with Stata MP V.13 (Stata).

**RESULTS**

There was much variation in the built environment characteristics across the three cities (table 1). Charleston had the highest percentage of green streets (79%), while Chicago had the highest percentage of streets with crosswalks (23%) and commercial buildings/apartments (56%). Figures 1–3 display the zip code distribution of the three built environment characteristics in the three cities as well as sample street view images. (Note: full-page figures are also reproduced in the online supplemental files, Figures S1–S9). In Salt Lake City, crosswalks were most common in central regions, commercial buildings/apartments were found in high density in a few small areas and street greenness was abundant in the eastern region. In Chicago, crosswalks and commercial buildings/apartments were prevalent across the city, with somewhat lower percentages for the most southern areas. In Charleston, crosswalks and green space were prominent in the most northern and southern areas. In Charleston, crosswalks and green space could be found across the region, while commercial buildings/apartments were concentrated in the south-western region.

In Salt Lake City, greater population density was marginally related to fewer commercial buildings/apartments and more green streets (see online supplemental table S1). Areas with more senior citizens had more green streets in Salt Lake City. Percentage of blacks was correlated with more crosswalks and more commercial buildings/apartments. Percentage of Hispanics was correlated with fewer crosswalks and fewer commercial buildings/apartments (online supplemental table S1). In Chicago,

Neighbourhood characteristics derived from street images collected between December 2016 and February 2017 from Google’s Street View Image API.
zip codes with more seniors and higher median household income had greener streets and fewer commercial buildings/apartments. In Charleston, population density was negatively associated with green streets. Zip codes with higher population density and higher percentage of young residents were less likely to have commercial buildings/apartments. Percentage of blacks was related to more commercial buildings/apartments and marginally more crosswalks (see online supplemental table S3). Analyses examining relationships at the census tract level generally showed similar associations as seen at the zip code level (online supplemental tables S4–S6), although at the tract level, it becomes more apparent that higher median household income was associated with more green streets and fewer commercial buildings/apartments.

Merging built environment indicators in Salt Lake City with individual-level health outcomes from the Utah Population Database, we examined the potential influences of neighbourhood characteristics on adult obesity and diabetes. Comparing the third tertile with the first tertile, more green streets (prevalence ratio (PR)=0.73; 95% CI 0.63 to 0.85), crosswalks (PR=0.76; 95% CI 0.69 to 0.85) and presence of commercial buildings/apartments (PR=0.79; 95% CI 0.67 to 0.94) were associated with lower individual obesity prevalence (table 2). More green streets (PR=0.86; 95% CI 0.77 to 0.96), crosswalks (PR=0.87; 95% CI 0.80 to 0.95) and presence of commercial buildings/apartments (PR=0.81; 95% CI 0.67 to 0.98) were also associated with lower individual diabetes prevalence (table 2). In sensitivity analyses, we adjust for birth weight, a predisposing factor...
for obesity and diabetes. Results were qualitatively similar (online supplemental table S7), but the sample size was smaller because analyses used only adults born in Utah. Analyses using continuous BMI also suggest that green streets and crosswalks were related to lower BMI (online supplemental table S8).

**DISCUSSION**

In this study, we demonstrate the feasibility and accuracy of computer vision models for automatic detection and characterisation of neighbourhood built environment features. Moreover, in piloting our algorithms across three visually and geographically distinct US cities, we found that the models were generally robust to varying landscapes. Group demographic characteristics correlated with built environment features, either suggesting differential access or preference for different types of neighbourhoods. Greater median family income was related to greener streets and fewer commercial buildings/apartments. In Chicago, greater median density was related to more commercial buildings/apartments, but in Charleston and Salt Lake City, the opposite was true, and suggested different forms of dominant housing and building types for more populous areas. Furthermore, in Salt Lake City, we found that green streets, crosswalks and commercial buildings/apartments were associated with lower individual prevalence of obesity and diabetes, controlling for predisposing characteristics.

**Study findings in context**

Previous studies have used Google Street View to perform virtual audits to assess walkability, physical disorder, retail alcohol stores and urban greenery among other neighbourhood characteristics. Researchers have also developed a Computer Assisted Neighborhood Visual Assessment System to allow users to conduct virtual neighbourhood audits of Google Street View images. Studies comparing the results of onsite audits and virtual audits have found good agreement across a range of measures. A study of 37 block faces in New York City found high levels of agreement for pedestrian safety, motorised traffic, parking and infrastructure. Assessment for physical disorder and neighbourhood characteristics that had fine details or temporal variability had lower levels of agreement. Moreover, research teams have begun to use automated approaches to extract neighbourhood features from Google Street View images such as pedestrian count and visual enclosure (ie, proportion sky visible from a point on the street)—measures associated with walkability. In this paper, we use street view images to extract additional neighbourhood characteristics and investigate their associations with chronic disease. Our findings are consistent with prior literature. Mix land uses, connected streets, higher residential density and attractive scenery promote physical activity.

*Data source for health outcomes: Utah Population database.†Adjusted Poisson models were run for each outcome separately. Models controlled for individual-level age, sex, race, ethnicity, education and marital status as well as zip code-level population density, percentage of the population 65 years and older, percentage of Hispanics, percentage of blacks, median household income and percentage of household living in current residence for 5 years or more. Built environment characteristics were categorised into tertiles, with the lowest tertile serving as the referent group. SEs were adjusted for clustering of values at the zip code level.

The neighbourhood built environment can impact health and health behaviours by locating either risks or resources for health. Thus far, characterising and investigating built environment features has generally been limited to local studies due to the resource-intensive nature of (1) site visits to create community inventories of features and (2) manual annotations of street images. In this study, we leveraged recent advancements in computer vision and the emergence of massive sources of street image data. We developed a data collection strategy using geographic information systems to assemble a collection of street intersection and street segment images for three cities in the USA. We implemented computer vision algorithms to produce neighbourhood summaries of built environment that have been theoretically and empirically identified to be important for health outcomes. We then investigated the potential impact of neighbourhood environments on chronic diseases using administrative records and medical records from a large healthcare provider, accounting for predisposing characteristics.

Nonetheless, our study has limitations. Like other modes of data collection, image data can only capture a subset of community features. For instance, we are unable to create indicators for noise (eg, hearing gunshots) and witnessing criminal activity. Even when the goal is a built environment characteristic, not all types of characteristics lend themselves to easy extraction from images and processing by computer vision algorithms. In preliminary analyses, we attempted to construct indicators of litter, but manual annotations of street images had low reliability between raters given the small size of litter and its resemblance to other small objects such as leaves. We also had difficulty obtaining enough training data for dilapidated buildings and graffiti because of their relative rarity. Ratings of neighbour- hood aesthetics (‘beauty’) varied greatly between raters. Characterising subjective qualities of a neighbourhood may require amassing resident and visitor perceptions to capture variability. César Hidalgo, Ramesh Raskar and colleagues used crowd-sourcing techniques to obtain labelled data on perceived safety of street views from cities across the USA and from these labelled data, they built machine learning algorithms to predict how safe the street image looks to a human observer.

Besides the type of neighbourhood features that can easily lend themselves to automatic extraction via computer vision models, the depth of neighbourhood features that can be extracted may be limited. Neighbourhood inventories created from onsite visits provide a wealth of fine-grain information about hundreds of different features. Building a computer vision model to accurately extract each of these hundreds of features would be a difficult task. Well-known neighbourhood audit instruments include the Irvine-Minnesota Inventory, the Pedestrian Environment Data Scan and the Maryland Inventory of Urban Design Qualities.
Another limitation was that analyses were cross-sectional, and thus the study was unable to evaluate longitudinal trends. The analyses did not take into account residential histories and the length of time individuals lived in the communities. We find links between built environment characteristics and chronic disease prevalence; however, our study was unable to identify the direction of causality. For instance, study participants’ chronic disease diagnoses may have preceded their time in a neighbourhood or their diagnoses may have prompted them to move into a different neighbourhood.

CONCLUSIONS

The epidemic rise in chronic health conditions is recent. This suggests that its cause is social, cultural and constructed rather than purely biological. Nonetheless, the dearth of data on contextual factors limits understanding of the influence of neighbourhood characteristics on health. We harness the underused potential of street image data to characterise built environments. Our substantive investigation of the impact of built neighbourhood characteristics on chronic conditions suggests that green streets, crosswalks and mix building types were related to lower obesity and diabetes prevalence. Results and data products can be used by city agencies and public health practitioners to inform strategies for improving community health.

What is already known on this subject

Neighbourhood characteristics have been associated with mental and physical health outcomes including chronic disease. However, the bulk of the literature has focused on small geographical locations due to the time and cost demands of neighbourhood audits of built environment characteristics.

What this study adds

In this study, we demonstrate the feasibility and accuracy of computer vision models for the automatic detection and characterisation of neighbourhood built environment features across three visually and geographically distinct cities. Investigating health outcomes in Salt Lake City, we found that green streets, crosswalks and commercial buildings/apartments were associated with lower individual obesity and diabetes prevalence, controlling for individual-level and zip code-level predisposing characteristics.
