The COVID-19 pandemic and health inequalities

Clare Bambra,1 Ryan Riordan,2 John Ford,2 Fiona Matthews1

ABSTRACT
This essay examines the implications of the COVID-19 pandemic for health inequalities. It outlines historical and contemporary evidence of inequalities in pandemics—drawing on international research into the Spanish influenza pandemic of 1918, the H1N1 outbreak of 2009 and the emerging international estimates of socio-economic, ethnic and geographical inequalities in COVID-19 infection and mortality rates. It then examines how these inequalities in COVID-19 are related to existing inequalities in chronic diseases and the social determinants of health, arguing that we are experiencing a syndemic pandemic. It then explores the potential consequences for health inequalities of the lockdown measures implemented internationally as a response to the COVID-19 pandemic, focusing on the likely unequal impacts of the economic crisis. The essay concludes by reflecting on the longer-term public health policy responses needed to ensure that the COVID-19 pandemic does not increase health inequalities for future generations.

PART 1. HISTORICAL AND CONTEMPORARY EVIDENCE OF INEQUALITIES IN PANDEMICS
More recent studies have confirmed Sydenstricker’s early findings: there were significant inequalities in the 1918 Spanish influenza pandemic. The international literature demonstrates that there were inequalities in prevalence and mortality rates: between high-income and low-income countries, and more and less affluent neighbourhoods, higher and lower socio-economic groups, and urban and rural areas. For example, India had a mortality rate 40 times higher than Denmark and the mortality rate was 20 times higher in some South American countries than in Europe. In Norway, mortality rates were highest among the working-class districts of Oslo; in the USA, they were highest among the unemployed and the urban poor in Chicago, and across Sweden, there were inequalities in mortality between the highest and lowest occupational classes—particularly among men. In contrast, countries with smaller pre-existing social and economic inequalities, such as New Zealand, did not experience any socio-economic inequalities in mortality.

INTRODUCTION
In 1931, Edgar Sydenstricker outlined inequalities by socio-economic class in the 1918 Spanish influenza epidemic in America, reporting a significantly higher incidence among the working classes. This challenged the widely held popular and scientific consensus of the time which held that ‘the flu hit the rich and the poor alike’. In the COVID-19 pandemic, there have been similar claims made by politicians and the media—that we are ‘all in it together’ and that the COVID-19 virus ‘does not discriminate’. This essay aims to dispel this myth of COVID-19 as a socially neutral disease, by discussing how, just as 100 years ago, there are inequalities in COVID-19 morbidity and mortality rates—reflecting existing unequal experiences of chronic diseases and the social determinants of health. The essay is structured in three main parts. Part 1 examines historical and contemporary evidence of inequalities in pandemics—drawing on international research into the Spanish influenza pandemic of 1918, the H1N1 outbreak of 2009 and the emerging international estimates of socio-economic, ethnic and geographical inequalities in COVID-19 infection and mortality rates. Part 2 examines how these inequalities in COVID-19 are related to existing inequalities in chronic diseases and the social determinants of health, arguing that we are experiencing a syndemic pandemic. In Part 3, we explore the potential consequences for health inequalities of the lockdown measures implemented internationally as a response to the COVID-19 pandemic, focusing on the likely unequal impacts of the economic crisis. The essay concludes by reflecting on the longer-term public health policy responses needed to ensure that the COVID-19 pandemic does not increase health inequalities for future generations.
Just as in 1918 and 2009, evidence of social inequalities is already emerging in relation to COVID-19 from Spain, the USA and the UK. Intermediate data published by the Catalanian government in Spain suggest that the rate of COVID-19 infection is six or seven times higher in the most deprived areas of the region compared to the least deprived. Similarly, in preliminary USA analysis, Chen and Krieger (2020) found area-level socio-spatial gradients in confirmed cases in Illinois and positive test results in New York City, with dramatically increased risk of death observed among residents of the most disadvantaged counties. With regard to ethnic inequalities in COVID-19, data from England and Wales have found that people who are black, Asian and minority ethnic (BAME) accounted for 34.5% of 4873 critically ill COVID-19 patients (in the period ending April 16, 2020) and much higher than the 11.5% seen for viral pneumonia between 2017 and 2019. Only 14% of the population of England and Wales are from BAME backgrounds. Even more stark is the data on racial inequalities in COVID-19 infections and deaths that are being released by various states and municipalities in the USA. For example, in Chicago (in the period ending April 17, 2020), 59.2% of COVID-19 deaths were among black residents and the COVID-19 mortality rate for black Chicagoans was 34.8 per 100 000 population compared to 8.2 per 100 000 population among white residents. There will likely be an interaction of race and socio-economic inequalities, demonstrating the intersectionality of multiple aspects of disadvantage coalescing to further compound illness and increase the risk of mortality.

### PART 2. THE SYNDEMIC OF COVID-19, CHRONIC DISEASE AND THE SOCIAL DETERMINANTS OF HEALTH

The COVID-19 pandemic is occurring against a backdrop of social and economic inequalities in existing non-communicable diseases (NCDs) as well as inequalities in the social determinants of health. Inequalities in COVID-19 infection and mortality rates are therefore arising as a result of a syndemic of COVID-19, inequalities in chronic diseases and the social determinants of health. The prevalence and severity of the COVID-19 pandemic is magnified because of the pre-existing epidemics of chronic disease—which are themselves socially patterned and associated with the social determinants of health. The concept of a syndemic was originally developed by Merrill Singer to help understand the relationships between HIV/AIDS, substance use and violence in the USA in the 1990s. A syndemic exists when risk factors or comorbidities are intertwined, interactive and cumulative—adversely exacerbating the disease burden and additively increasing its negative effects: ‘A syndemic is a set of closely intertwined and mutual enhancing health problems that significantly affect the overall health status of a population within the context of a perpetuating configuration of noxious social conditions’ [24 p13]. We argue that for the most disadvantaged communities, COVID-19 is experienced as a syndemic—a co-occurring, synergistic pandemic that interacts with and exacerbates their existing NCDs and social conditions (figure 1).

Minority ethnic groups, people living in areas of higher socio-economic deprivation, those in poverty and other marginalised groups (such as homeless people, prisoners and street-based sex workers) generally have a greater number of coexisting NCDs, which are more severe and experienced at a younger age. For example, people living in more socio-economically disadvantaged neighbourhoods and minority ethnic groups have higher rates of almost all of the known underlying clinical risk factors that increase the severity and mortality of COVID-19, including hypertension, diabetes, asthma, chronic obstructive pulmonary disease (COPD), heart disease, liver disease, renal disease, cancer, cardiovascular disease, obesity and smoking. Likewise, minority ethnic groups in Europe, the USA and other high-income countries experience higher rates of the key COVID-19 risk factors, including coronary heart disease and diabetes. Similarly, the Gypsy/Roma community—one of the most marginalised minority groups in Europe—has a smoking rate that is two to three times the European average and increased rates of respiratory diseases (such as COPD) and other COVID-19 risk factors.

These inequalities in chronic conditions arise as a result of inequalities in exposure to the social determinants of health: the conditions in which people ‘live, work, grow and age’ including working conditions, unemployment, access to essential goods and services (eg, water, sanitation and food), housing and access to healthcare. By way of example, there are considerable occupational inequalities in exposure to adverse working conditions (eg, ergonomic hazards, repetitive work, long hours, shift work, low wages, job insecurity)—they are concentrated in lower-skill jobs. These working conditions are associated with increased risks of respiratory diseases, certain cancers, musculoskeletal disease, hypertension, stress and anxiety. In addition to these long-term exposures, inequalities in working conditions may well be impacting the unequal distribution of the COVID-19 disease burden. For example, lower-paid workers (where BAME groups are disproportionately represented)—particularly in the service sector (eg, food, cleaning or delivery services)—are much more likely to be designated as key workers and thereby are still required to go to work and rely on public transport for doing so. All these increase their exposure to the virus.

Similarly, access to healthcare is lower in disadvantaged and marginalised communities—even in universal healthcare systems. In England, the number of patients per general practitioners is 15% higher in the most deprived areas than in the least deprived areas. Medical care is even more equally...
distributed in countries such as the USA where around 33 million
Americans—from the most disadvantaged and marginalised
groups—have insufficient or no healthcare insurance.27 This
reduced access to healthcare—before and during the outbreak
—contributes to inequalities in chronic disease and is also likely
to lead to worse outcomes from COVID-19 in more disadvan-
taged areas and marginalised communities. People with existing
chronic conditions (eg, cancer or cardiovascular disease (CVD))
are less likely to receive treatment and diagnosis as health services
are overwhelmed by dealing with the pandemic.

Housing is also an important factor in driving health
inequalities.34 For example, exposure to poor quality housing is
associated with certain health outcomes, for example, damp
housing can lead to respiratory diseases such as asthma while
overcrowding can result in higher infection rates and increased
risk of injury from household accidents.34 Housing also impacts
health inequalities materially through costs (eg, as a result of high
rents) and psychosocially through insecurity (eg, short-term
leases).34 Lower socio-economic groups have a higher exposure
to poor quality or unaffordable, insecure housing and therefore
have a higher rate of negative health consequences.35 These
inequalities in housing conditions may also be contributing to
inequalities in COVID-19. For example, deprived neighbour-
hoods are more likely to contain houses of multiple occupation
and smaller houses with a lack of outside space, as well as have
higher population densities (particularly in deprived urban areas)
and lower access to communal green space.27 These will likely
increase COVID-19 transmission rates—as was the case with
H1N1 where strong associations were found with urbanity.13

The social determinants of health also work to make people
from marginalised communities more vulnerable to infection
from COVID-19—even when they have no underlying health
conditions. Decades of research into the psychosocial determi-
nants of health have found that the chronic stress of material
and psychological deprivation is associated with immunosuppression.36 Psychosocial feelings of subordination or inferiority as a result of occupying a low position on the social
hierarchy stimulate physiological stress responses (eg, raised cor-
tisol levels), which, when prolonged (chronic), can have long-
term adverse consequences for physical and mental health.37 By
way of example, studies have found consistent associations
between low job status (eg, low control and high demands),
stress-related morbidity and various chronic conditions including
coronary heart disease, hypertension, obesity, musculoskeletal
conditions, and psychological ill health.38 Likewise, there is
increasing evidence that living in disadvantaged environments
may produce a sense of powerlessness and collective threat
among residents, leading to chronic stressors that, in time,
damage health.39 Studies have also confirmed that adverse psy-
chosocial circumstances increase susceptibility— influencing the
onset, course and outcome of infectious diseases— including
respiratory diseases like COVID-19.40

PART 3. THE GREAT LOCKDOWN: THE COVID-19 ECONOMIC
CRISIS AND HEALTH INEQUALITIES

The impact of COVID-19 on health inequalities will not just be in
terms of virus-related infection and mortality, but also in terms of
the health consequences of the policy responses undertaken in
most countries. While traditional public health surveillance mea-
sures of contact tracing and individual quarantine were success-
fully pursued by some countries (most notably by South Korea
and Germany) as a way of tackling the virus in the early stages,
most other countries failed to do so, and governments worldwide
were eventually forced to implement mass quarantine measures
—in the form of lockdowns. These state-imposed restrictions—
usually requiring the government to take on emergency powers—
have been implemented to varying levels of severity, but all have
in common a significant increase in social isolation and confine-
ment within the home and immediate neighbourhood. The aims of
these unprecedented measures are to increase social and phy-
sical distancing and thereby reduce the effective reproduction
number (R0) of the virus to less than 1. For example, in the
UK, individuals were only allowed to leave the home for one of
four reasons (shopping for basic necessities, exercise, medical
needs, travelling for work purposes). Following Wuhan province
in China, most of the lockdowns have been implemented for 8 to
12 weeks.

The immediate pathways through which the COVID-19 emer-
gency lockdowns are likely to have unequal health impacts are
multiple—ranging from unequal experiences of lockdown (eg,
due to job and income loss, overcrowding, urbanity, access to
green space, key worker roles), how the lockdown itself is shap-
ing the social determinants of health (eg, reduced access to
healthcare services for non-COVID-19 reasons as the system is
overwhelmed by the pandemic) and inequalities in the immediate
health impacts of the lockdown (eg, in mental health and gender-
based violence). However, arguably, the longer-term and largest
consequences of the ‘great lockdown’ for health inequalities will
be through political and economic pathways (figure 1). The
world economy has been severely impacted by COVID-19—
with almost daily record stock market falls, oil prices have
plunged and there are record levels of unemployment (eg, 5.2
million people filed for unemployment benefit in just 1 week in
April 2020 in the USA), despite the unprecedented intervention-
ist measures undertaken by some governments and central banks
—such as the £300 billion injection by the UK government to
support workers and businesses. The pandemic has slowed
China’s economy with a predicted loss of $65 billion as a mini-
num in the first quarter of 2020. Economists fear that the eco-
nomic impact will be far greater than the financial crisis of 2007/
2008, and they say that it is likely to be worse in depth than the
Great Depression of the 1930s. Just like the 1918 influenza
pandemic (which had severe impacts on economic performance
and increased poverty rates), the COVID-19 crisis will have huge
economic, social and—ultimately—health consequences.

Previous research has found that sudden economic shocks (like
the collapse of communism in the early 1990s and the global
financial crisis (GFC) of 200841) lead to increases in morbidity,
mental ill health, suicide and death from alcohol and substance
use. For example, following the GFC, worldwide an excess of
suicides were observed in the USA, England, Spain and Ireland.42
There is also evidence of other increases in poor mental health
after the GFC including self-harm and psychiatric morbidity.41 42
These health impacts were not shared equally though—areas of
the UK with higher unemployment rates had greater increases in
suicide rates and inequalities in mental health increased with
people living in the most deprived areas experiencing the largest
 Increases in psychiatric morbidity and self-harm.43 44 Further,
unemployment (and its well-established negative health impacts
in terms of morbidity and mortality) is disproportionately
experienced by those with lower skills or who live in less buoyant
local labour markets.25 So, the health consequences of the
COVID-19 economic crisis are likely to be similarly unequally
distributed—exacerbating health inequalities.

However, the effects of recessions on health inequalities also
vary by public policy response with countries such as the UK,
Greece, Italy and Spain who imposed austerity (significant cuts in

health and social protection budgets) after the GFC experiencing worse population health effects than those countries such as Germany, Iceland and Sweden who opted to maintain public spending and social safety nets.41 Indeed, research has found that countries with higher rates of social protection (such as Sweden) did not experience increases in health inequalities during the 1990s economic recession.44 Similarly, old-age pensions in the UK were protected from austerity cuts after the GFC and research has suggested that this prevented health inequalities increasing amongst the older population.43 These findings are in keeping with previous studies of the effects of public sector and welfare state contractions and expansions on trends in health inequalities in the UK, USA and New Zealand.57 46–48 For example, inequalities in premature mortality and infant mortality by income and ethnicity in the USA decreased during the period of welfare expansion in the USA (‘war on poverty’ era 1966 to 1980), but they increased again during the Reagan–Bush period (1980–2002) when welfare services and healthcare coverage were cut.46 Similarly, in England, inequalities in infant mortality rates reduced as child poverty decreased in a period of public sector and welfare state expansion (from 2000 to 2010),47 but increased again when austerity was implemented and child poverty rates increased (from 2010 to 2017).48

CONCLUSION
So this essay makes for grim reading for researchers, practitioners and policymakers concerned with health inequalities. Historically, pandemics have been experienced unequally with higher rates of infection and mortality among the most disadvantaged communities—particularly in more socially unequal countries.9 11 Emerging evidence from a variety of countries suggests that these inequalities are being mirrored today in the COVID-19 pandemic. Both then and now, these inequalities have emerged through the syndemic nature of COVID-19—as it interacts with and exacerbates existing social inequalities in chronic disease and the social determinants of health. COVID-19 has laid bare our longstanding social, economic and political inequalities - even before the COVID-19 pandemic, life expectancy amongst the poorest groups was already declining in the UK and the USA and health inequalities in some European countries have been increasing over the last decade.50 It seems likely that there will be a post-COVID-19 global economic slump—which could make the health equity situation even worse, particularly if health-damaging policies of austerity are implemented again. It is vital that this time, the right public policy responses (such as expanding social protection and public services and pursuing green inclusive growth strategies) are undertaken so that the COVID-19 pandemic does not increase health inequalities for future generations. Public health must ‘win the peace’ as well as the ‘war’.
