The COVID-19 pandemic and health inequalities

Clare Bambra,1 Ryan Riordan,2 John Ford,2 Fiona Matthews1

ABSTRACT

This essay examines the implications of the COVID-19 pandemic for health inequalities. It outlines historical and contemporary evidence of inequalities in pandemics—drawing on international research into the Spanish influenza pandemic of 1918, the H1N1 outbreak of 2009 and the emerging international estimates of socio-economic, ethnic and geographical inequalities in COVID-19 infection and mortality rates. It then examines how these inequalities in COVID-19 are related to existing inequalities in chronic diseases and the social determinants of health, arguing that we are experiencing a syndemic pandemic. It then explores the potential consequences for health inequalities of the lockdown measures implemented internationally as a response to the COVID-19 pandemic, focusing on the likely unequal impacts of the economic crisis. The essay concludes by reflecting on the longer-term public health policy responses needed to ensure that the COVID-19 pandemic does not increase health inequalities for future generations.

PART 1. HISTORICAL AND CONTEMPORARY EVIDENCE OF INEQUALITIES IN PANDEMICS

More recent studies have confirmed Sydenstricker’s early findings: there were significant inequalities in the 1918 Spanish influenza pandemic. The international literature demonstrates that there were inequalities in prevalence and mortality rates: between high-income and low-income countries, and more and less affluent neighbourhoods, higher and lower socio-economic groups, and urban and rural areas. For example, India had a mortality rate 40 times higher than Denmark and the mortality rate was 20 times higher in some South American countries than in Europe. In Norway, mortality rates were highest among the working-class districts of Oslo; in the USA, they were highest among the unemployed and the urban poor in Chicago, and across Sweden, there were inequalities in mortality between the highest and lowest occupational classes—particularly among men. In contrast, countries with smaller pre-existing social and economic inequalities, such as New Zealand, did not experience any socio-economic inequalities in mortality. An urban–rural effect was also observed in the 1918 influenza pandemic whereby, for example, in England and Wales, the mortality was 30%–40% higher in urban areas. There is also some evidence from the USA that the pandemic had long-term impacts on inequalities in child health and development.

Several studies have also demonstrated inequalities in the 2009 H1N1 influenza pandemic. For example, globally, Mexico experienced a higher mortality rate than that in higher-income countries. In terms of socio-economic inequalities, the mortality rate from H1N1 in the most deprived neighbourhoods of England was three times higher than in the least deprived. It was also higher in urban compared to rural areas. Similarly, a Canadian study in Ontario found that hospitalisation rates for H1N1 were associated with lower educational attainment and living in a high deprivation neighbourhood. Another study found positive associations between people with financial issues (eg, financial barriers to healthcare access) and influenza-like illnesses during the 2009 H1N1 pandemic in the USA. Various studies on cyclical winter influenza in North America have also found associations between mortality, morbidity and symptom severity and socio-economic status among adults and children.
PART 2. THE SYNDEMIC OF COVID-19, CHRONIC DISEASE AND THE SOCIAL DETERMINANTS OF HEALTH

The COVID-19 pandemic is occurring against a backdrop of social and economic inequalities in existing non-communicable diseases (NCDs) as well as inequalities in the social determinants of health. Inequalities in COVID-19 infection and mortality rates are therefore arising as a result of a syndemic of COVID-19, inequalities in chronic diseases and the social determinants of health. The prevalence and severity of the COVID-19 pandemic is magnified because of the pre-existing epidemics of chronic disease—which are themselves socially patterned and associated with the social determinants of health. The concept of a syndemic was originally developed by Merrill Singer to help understand the relationships between HIV/AIDS, substance use and violence in the USA in the 1990s. A syndemic exists when risk factors or comorbidities are intertwined, interactive and cumulative—and adversely exacerbating the disease burden and additively increasing its negative effects: ‘A syndemic is a set of closely intertwined and mutual enhancing health problems that significantly affect the overall health status of a population within the context of a perpetuating configuration of noxious social conditions’ [24 p13]. We argue that for the most disadvantaged communities, COVID-19 is experienced as a syndemic—a co-occurring, synergistic pandemic that interacts with and exacerbates their existing NCDs and social conditions (figure 1).

Minority ethnic groups, people living in areas of higher socio-economic deprivation, those in poverty and other marginalised groups (such as homeless people, prisoners and street-based sex workers) generally have a greater number of coexisting NCDs, which are more severe and experienced at a younger age. For example, people living in more socio-economically disadvantaged neighbourhoods and minority ethnic groups have higher rates of almost all of the known underlying clinical risk factors that increase the severity and mortality of COVID-19, including hypertension, diabetes, asthma, chronic obstructive pulmonary disease (COPD), heart disease, liver disease, renal disease, cancer, cardiovascular disease, obesity and smoking. Likewise, minority ethnic groups in Europe, the USA and other high-income countries experience higher rates of the key COVID-19 risk factors, including coronary heart disease and diabetes. Similarly, the Gypsy/Roma community—one of the most marginalised minority groups in Europe—has a smoking rate that is two to three times the European average and increased rates of respiratory diseases (such as COPD) and other COVID-19 risk factors.

These inequalities in chronic conditions arise as a result of inequalities in exposure to the social determinants of health: the conditions in which people ‘live, work, grow and age’ including working conditions, unemployment, access to essential goods and services (eg, water, sanitation and food), housing and access to healthcare. By way of example, there are considerable occupational inequalities in exposure to adverse working conditions (eg, ergonomic hazards, repetitive work, long hours, shift work, low wages, job insecurity)—they are concentrated in lower-skill jobs. These working conditions are associated with increased risks of respiratory diseases, certain cancers, musculoskeletal disease, hypertension, stress and anxiety. In addition to these long-term exposures, inequalities in working conditions may well be impacting the unequal distribution of the COVID-19 disease burden. For example, lower-paid workers (where BAME groups are disproportionately represented)—particularly in the service sector (eg, food, cleaning or delivery services)—are much more likely to be designated as key workers and thereby are still required to go to work and rely on public transport for doing so. All these increase their exposure to the virus.

Similarly, access to healthcare is lower in disadvantaged and marginalised communities—even in universal healthcare systems. In England, the number of patients per general practitioner is 15% higher in the most deprived areas than that in the least deprived areas. Medical care is even more unequally
distributed in countries such as the USA where around 33 million Americans—from the most disadvantaged and marginalised groups—have insufficient or no healthcare insurance. This reduced access to healthcare—before and during the outbreak—contributes to inequalities in chronic disease and is also likely to lead to worse outcomes from COVID-19 in more disadvantaged areas and marginalised communities. People with existing chronic conditions (eg, cancer or cardiovascular disease (CVD)) are less likely to receive treatment and diagnosis as health services are overwhelmed by dealing with the pandemic.

Housing is also an important factor in driving health inequalities. For example, exposure to poor quality housing is associated with certain health outcomes, for example, damp housing can lead to respiratory diseases such as asthma while overcrowding can result in higher infection rates and increased risk of injury from household accidents. Housing also impacts health inequalities materially through costs (eg, as a result of high rents) and psychologically through insecurity (eg, short-term leases). Lower socio-economic groups have a higher exposure to poor quality or unaffordable, insecure housing and therefore have a higher rate of negative health consequences. These inequalities in housing conditions may also be contributing to inequalities in COVID-19. For example, deprived neighbourhoods are more likely to contain houses of multiple occupation and smaller houses with a lack of outside space, as well as have higher population densities (particularly in deprived urban areas) and lower access to communal green space. These will likely increase COVID-19 transmission rates—as was the case with H1N1 where strong associations were found with urbanity.

The social determinants of health also work to make people from marginalised communities more vulnerable to infection from COVID-19—even when they have no underlying health conditions. Decades of research into the psychosocial determinants of health have found that the chronic stress of material and psychological deprivation is associated with immunosuppression. Psychosocial feelings of subordination or inferiority as a result of occupying a low position on the social hierarchy stimulate physiological stress responses (eg, raised cortisol levels), which, when prolonged (chronic), can have long-term adverse consequences for physical and mental health. By way of example, studies have found consistent associations between low job status (eg, low control and high demands), stress-related morbidity and various chronic conditions including coronary heart disease, hypertension, obesity, musculoskeletal conditions, and psychological ill health. Likewise, there is increasing evidence that living in disadvantaged environments may produce a sense of powerlessness and collective threat among residents, leading to chronic stressors that, in time, damage health. Studies have also confirmed that adverse psychosocial circumstances increase susceptibility— Influencing the onset, course and outcome of infectious diseases—including respiratory diseases like COVID-19.

PART 3. THE GREAT LOCKDOWN: THE COVID-19 ECONOMIC CRISIS AND HEALTH INEQUALITIES

The impact of COVID-19 on health inequalities will not just be in terms of virus-related infection and mortality, but also in terms of the health consequences of the policy responses undertaken in most countries. While traditional public health surveillance measures of contact tracing and individual quarantine were successfully pursued by some countries (most notably by South Korea and Germany) as a way of tackling the virus in the early stages, most other countries failed to do so, and governments worldwide were eventually forced to implement mass quarantine measures—in the form of lockdowns. These state-imposed restrictions—usually requiring the government to take on emergency powers—have been implemented to varying levels of severity, but all have in common a significant increase in social isolation and confinement within the home and immediate neighbourhood. The aims of these unprecedented measures are to increase social and physical distancing and thereby reduce the effective reproduction number (R0) of the virus to less than 1. For example, in the UK, individuals were only allowed to leave the home for one of four reasons (shopping for basic necessities, exercise, medical needs, travelling for work purposes). Following Wuhan province in China, most of the lockdowns have been implemented for 8 to 12 weeks.

The immediate pathways through which the COVID-19 emergency lockdowns are likely to have unequal health impacts are multiple—ranging from unequal experiences of lockdown (eg, due to job and income loss, overcrowding, urbanity, access to green space, key worker roles), how the lockdown itself is shaping the social determinants of health (eg, reduced access to healthcare services for non-COVID-19 reasons as the system is overwhelmed by the pandemic) and inequalities in the immediate health impacts of the lockdown (eg, in mental health and gender-based violence). However, arguably, the longer-term and largest consequences of the ‘great lockdown’ for health inequalities will be through political and economic pathways (figure 1). The world economy has been severely impacted by COVID-19—with almost daily record stock market falls, oil prices have crashed and there are record levels of unemployment (eg, 5.2 million people filed for unemployment benefit in just 1 week in April 2020 in the USA), despite the unprecedented interventionist measures undertaken by some governments and central banks—such as the £300 billion injection by the UK government to support workers and businesses. The pandemic has slowed China’s economy with a predicted loss of $65 billion as a minimum in the first quarter of 2020. Economists fear that the economic impact will be far greater than the financial crisis of 2007/2008, and they say that it is likely to be worse in depth than the Great Depression of the 1930s. Just like the 1918 influenza pandemic (which had severe impacts on economic performance and increased poverty rates), the COVID-19 crisis will have huge economic, social and—ultimately—health consequences.

Previous research has found that sudden economic shocks (like the collapse of communism in the early 1990s and the global financial crisis (GFC) of 2008) lead to increases in morbidity, mental ill health, suicide and death from alcohol and substance use. For example, following the GFC, worldwide an excess of suicides were observed in the USA, England, Spain and Ireland. There is also evidence of other increases in poor mental health after the GFC including self-harm and psychiatric morbidity. These health impacts were not shared equally though—areas of the UK with higher unemployment rates had greater increases in suicide rates and inequalities in mental health increased with people living in the most deprived areas experiencing the largest increases in psychiatric morbidity and self-harm. Further, unemployment (and its well-established negative health impacts in terms of morbidity and mortality) is disproportionately experienced by those with lower skills or who live in less buoyant local labour markets. So, the health consequences of the COVID-19 economic crisis are likely to be similarly unequally distributed—exacerbating health inequalities.

However, the effects of recessions on health inequalities also vary by public policy response with countries such as the UK, Greece, Italy and Spain who imposed austerity (significant cuts in...
health and social protection budgets) after the GFC experiencing worse population health effects than those countries such as Germany, Iceland and Sweden who opted to maintain public spending and social safety nets.41 Indeed, research has found that countries with higher rates of social protection (such as Sweden) did not experience increases in health inequalities during the 1990s economic recession.42 Similarly, old-age pensions in the UK were protected from austerity cuts after the GFC and research has suggested that this prevented health inequalities increasing amongst the older population.43 These findings are in keeping with previous studies of the effects of public sector and welfare state contractions and expansions on trends in health inequalities in the UK, USA and New Zealand.44 46 47 For example, inequalities in premature mortality and infant mortality by income and ethnicity in the USA decreased during the period of welfare expansion in the USA (‘war on poverty’ era 1966 to 1980), but they increased again during the Reagan–Bush period (1980–2002) when welfare services and healthcare coverage were cut.46 Similarly, in England, inequalities in infant mortality rates reduced as child poverty decreased in a period of public sector and welfare state expansion (from 2000 to 2010),47 but increased again when austerity was implemented and child poverty rates increased (from 2010 to 2017).48

CONCLUSION
So this essay makes for grim reading for researchers, practitioners and policymakers concerned with health inequalities. Historically, pandemics have been experienced unequally with higher rates of infection and mortality among the most disadvantaged communities—particularly in more socially unequal countries.9 10 Emerging evidence from a variety of countries suggests that these inequalities are being mirrored today in the COVID-19 pandemic. Both then and now, these inequalities have emerged through the syndemic nature of COVID-19—as it interacts with and exacerbates existing social inequalities in chronic disease and the social determinants of health. COVID-19 has laid bare our longstanding social, economic and political inequalities— even before the COVID-19 pandemic, life expectancy amongst the poorest groups was already declining in the UK and the USA and health inequalities in some European countries have been increasing over the last decade.30 It seems likely that there will be a post-COVID-19 global economic slump—which could make the health equity situation even worse, particularly if health-damaging policies of austerity are implemented again. It is vital that this time, the right public policy responses (such as expanding social protection and public services and pursuing green inclusive growth strategies) are undertaken so that the COVID-19 pandemic does not increase health inequalities for future generations. Public health must ‘win the peace’ as well as the ‘war’.
